LIST OF CONTRIBUTORS TO VOLUME CXIV.

Those whose names are marked with an asterisk have contributed editorial articles.

- ABRAMS, MARC V., M. D., Brooklyn.
 ALLPORT, FRANK, M. D., Chicago.
 ANDREWS, GEORGE C., M. D.
 ARNOLD, J. O., M. D., Philadelphia.
- BALL, CHARLES R., M. D., St. Paul.
 BARACH, JOSEPH H., M. D., Pittsburgh.
 BARNES, F. H., M. D., Stamford, Conn.
 BARTLE, HENRY J., B. S., M. D., Philadelphia.
 BEARD, STANLEY B., Ph. B., Pearl River, N. Y.
 BEASLEY, THOMAS J., M. D., Indianapolis.
 BEHREND, MOSES, M. D., Philadelphia.
 BENJAMIN, HARRY, M. D.
 BERMAN, L., M. D.
 BLUMENFELD, LOUIS, M. D., Brooklyn.
 BLUMGARTEN, A. S., M. D., F. A. C. P.
 BOGGS, RUSSELL H., M. D., Pittsburgh, Pa.
 BRADLEY, WILLIAM N., M. D., Philadelphia.
 BRADY, WILLIAM, M. D., Canandaigua, N. Y.
 BRAV, AARON, M. D., Philadelphia.
 BRENNER, I. M., M. D.
 BREWER, ISAAC W., M. D., Watertown, N. Y.
 *BRINK, LOUISE, A. B.
 BROADMAN, JOSEPH, M. D.
 BUCKSTEIN, JACOB, B. S., M. D.
 BUGBEE, H. G., M. D.
 BULKLEY, L. DUNCAN, A. M., M. D.
 BURBANK, REGINALD, M. D.
 BURR, CHARLES W., M. D., Philadelphia.
- CALLISON, JAMES G., M. D.
 CHERRY, THOMAS H., M. D., F. A. C. S.
 CLAIBORNE, J. HERBERT, M. D.
 CLOCK, RALPH OAKLEY, M. D., Pearl River, N. Y.
 *CLOUTING, CHARLES A., M. D., London.
 COHEN, HARRY, M. D.
 COHEN, SAMUEL, M. D., Philadelphia.
 COLLINS, D. W., M. D., Wilkes-Barre, Pa.
 COON, C. E., M. D., Syracuse, N. Y.
 COVEY, CLYDE B., M. D., Waukesha, Wis.
 *CUMSTON, CHARLES GREENE, M. D., Geneva, Switzerland.
 CURTIS, G. LENOX, M. D.
- *DONNELLY, WILLIAM HENRY, M. D., Brooklyn, N. Y.
 DRUECK, CHARLES J., M. D., Chicago.
 DYER, MARSHALL W., M. D., Syracuse, N. Y.
 EINHORN, MAX, M. D.
 *ELLIOTT, GEORGE, M. D., Toronto.
 ELLISON, RICHARD T., B. S., M. D., Philadelphia.
 ELMER, WALTER G., M. D., Philadelphia.
 EPSTEIN, J., M. D.
- FINKELSTEIN, HARRY, M. D.
 *FOSTER, MATTHIAS LANCKTON, M. D., New Rochelle, N. Y.
 *FRIDENBERG, PERCY, M. D.
 FRIEDENWALD, JULIUS, M. D., Baltimore.
 FRIEDMAN, E. D., M. D.
 FRIEDMAN, G. A., M. D.
 FRIEDMAN, JOSEPH, M. D.
 FRISCHMAN, LOUIS, M. D.
 FULD, JOSEPH E., M. D.
- GALLAND, WILLIAM H., M. D., F. A. C. S., Croton-on-the-Hudson, N. Y.
 GARRETSON, WILLIAM V. P., M. D.
 GERSTLEY, JESSE R., M. D., Chicago.
 GETELMAN, RALPH, M. D., Philadelphia.
 GEYSER, ALBERT C., M. D.
 GILBRIDE, JOHN J., A. M., M. D.
 GILF, BEN CLARK, M. D., Philadelphia.
 GITTINGS, J. CLAXTON, M. D., Philadelphia.
 GLEY, E., M. D., Paris, France.
 GOLDSTEIN, HYMAN I., M. D., Camden, N. J.
 GOODMAN, HERMAN, B. S., M. D.
 GOTTLIEB, MARK J., M. D.
 GRAHAM, HENRY FLACK, M. D., F. A. C. S., Brooklyn, N. Y.
 GRAHAM, JOHN RANDOLPH, M. D.
 GREENFIELD, SAMUEL D., M. D.
 GRIFFITH, J. P. CROZER, M. D., Philadelphia.
 GROSZMAN, WALDEMAR H., M. D., Plainfield, N. J.
 GUTMAN, JACOB, M. D., F. A. C. P., Brooklyn, N. Y.
- HADJPOPOULOS, L. G., M. D.
 HALPERT, HENRY, M. D., Scranton, Pa.
 HAMILTON, JAMES A., Ph. D.
 HAMMAR, J. AUG., M. D., Upsala, Sweden.
 HARRIS, LOUIS J., M. D.
 HELLER, ISAAC M., M. D.
 HERB, FERDINAND, M. D., Chicago.
 HERRMAN, CHARLES, M. D.
 HERRMAN, WILLIAM G., M. D., Asbury Park, N. J.
- HILL, C. D., M. D., Jersey City, N. J.
 HIRST, BARTON COOKE, M. D., Philadelphia.
 HIRST, JOHN COOKE, M. D., Philadelphia.
 HOPKINS, ARTHUR H., B. S., M. D., Philadelphia.
 HUPP, FRANK LEMOYNE, M. D., Wheeling, W. Va.
 HYMANSON, A., M. D.
- IRISH, WILLIAM HADDEN, M. D.
 ITTELSON, M. S., M. D., Brooklyn.
- JACK, GEORGE N., M. D., Buffalo, N. Y.
 *JELLIFFE, SMITH ELY, M. D., Ph. D.
 JOHNSTON, HOWARD M., D. D. S., Berkeley, Cal.
- KAIN, ALFRED, M. D.
 KAPLAN, D. M., M. D.
 KEILTY, ROBERT A., M. D., Danville, Pa.
 *KELLOGG, ELENORE.
 KELLOGG, WILLIAM A., M. D.
 KELLY, HOWARD, M. D., Baltimore.
 KENERSON, VERTNER, M. D., Buffalo, N. Y.
 KENWORTHY, MARION E., M. D.
 *KERBY, ERNEST F., M. D.
 KILDUFFE, ROBERT A., A. M., M. D., Pittsburgh.
 *KING, DOUGLAS, M. D.
 *KNOPF, S. ADOLPHUS, M. D.
 KOHN, L. WINFIELD, M. D.
 KOUNDJY, PIERRE, M. D., Paris.
 KRABBE, KNUD H., M. D., Copenhagen.
 KRAUS, WALTER M., A. M., M. D.
 KYRIDES, L. P., A. B., Sc. D.
- LADD, MAYNARD, M. D., Boston.
 LANDSMAN, ARTHUR A., M. D.
 LAPENTA, VINCENT ANTHONY, M. D., Indianapolis.
 LAZARUS, DAVID, M. D.
 LEAHY, SYLVESTER R., M. D.
 LEINER, JOSHUA H., M. D.
 LEY, GORDON, M. D., London.
 LIMERICK, O. VICTOR, M. D.
 LOESER, DAVID, Ph. G.
 LOWENBURG, HARRY, A. M., M. D., Philadelphia.
 LYNNAH, HENRY LOWNDES, M. D.
 LYON, B. B. VINCENT, A. M., M. D., Philadelphia.
- McBRAYER, R., A. B., M. D., Sanatorium, N. C.
 MacFARLANE, ANDREW, M. D., Albany, N. Y.
 McGUIRE, FRANK W., M. D., F. A. C. S., Buffalo, N. Y.

- MACKEE, GEORGE M., M. D.
 MCKENNA, WILLIAM FRANCIS, M. D.,
 Brooklyn.
 MCKENNEY, DESCUM C., M. D., F. A.
 C. S., Buffalo, N. Y.
 MCNUITY, JOHN J., M. D.
 MAGID, M. O., M. D.
 MANTON, W. P., M. D., F. A. C. S.,
 Detroit.
 *MAYO, CASWELL A., Phar. D., Cincin-
 nati, Ohio.
 MEAGHER, JOHN F. W., M. D., F. A.
 C. P., Brooklyn, N. Y.
 MEDING, C. B., M. D.

LIST OF ILLUSTRATIONS TO VOLUME CXIV

	PAGE		PAGE
Adrenal cortex and sexual development. Two Illustrations	7	Lung mapping. Five Illustrations.....	83-85
Aspergillosis and pulmonary pseudotuberculosis. Three Illustrations	630	Medical supervision of destitute children. Eleven Illustrations	200-204
Bronchoscopic foreign body extraction complicated by piopneumothorax. Six Illustrations	617-619	Mental deficiency, treatment for. One Illustration	231
Bucky diaphragm. Nine Illustrations	444-445	Method of refilling container for administering fluids. One Illustration	313
Crime and drug habit. Four charts	355-356	Mobilization of bony ankylosis of knee joint—arthroplasty. Six Illustrations	566-567
Diet in Infancy, with special reference to employment of Czerny and Kleinschmidt's butter flour mixture. Three Illustrations	140-141	Nephritis, unilateral. Seven Illustrations..	516-519
Duodenum, action on liver of salts introduced into. Nineteen Illustrations	263-269	Neuralgias of superior and inferior maxillary branches of fifth nerve. Seven Illustrations.	89-91
Dysmenorrhea. One Illustration	396	Pituitary extract, effect of, on rate of urine formation in man. One Illustration	54
Endothermy in accessible malignancy. Four Illustrations	686-687	Putnam, James J. Portrait	306
Endothermy in malignancy and precancerous conditions. Five Illustrations.....	379-380	Radiography, elimination of secondary radiation in. Three Illustrations	447-448
Feeding the sick. Two Illustrations.....	610	Recurrent pleurisy, treatment of, by injection of oxygen. Five Illustrations	624-625
Fracture of femur, treatment of. Twelve Illustrations	569-572	Röntgen ray therapy in chronic diseases of bones, joints and tendons. Two Illustrations	450
Gastric analysis, with detail of method and consideration of maximum of information to be obtained. Ten charts. Four Illustrations..	274-279	Salts introduced into duodenum and their action on the liver. Nineteen Illustrations.....	263-269
Gastric cases, interesting. Two Illustrations...	290	Schellberg treatment for chronic colonic infections. Eight Illustrations	107-109
Hand injuries, restoration of, by plastic surgery. Twenty-nine Illustrations	693-698	Smith, Stephen. Portrait	604
Hepatic fever due to gumma of liver. Two Illustrations	475-476	Stone in ureter voided after fulguration. Four Illustrations	523-524
Hippocrates. Portrait	186	Syracuse clinic. Four Illustrations.....	240-241
Hamsun, Knut. Portrait	548	Thoracic tumor mistaken for aneurysm. Two Illustrations	579
Infant feeding, unemphasized essentials in. Two charts	161	Tonsil enucleation and tonsil enucleator. One Illustration	640
Influenza as primary edema of respiratory mucous membranes and adnexa. Five Illustrations	653-654	Tonsil forceps, new. One Illustration	250
Inguinal hernia and appendix operation. Eleven Illustrations	343-344	Tuberculosis, etiology and elimination of. Two Illustrations	115
Keen, William Williams. Portrait	64	Twin tubal pregnancy. Two Illustrations	404
Laryngeal speculum, new. Two Illustrations..	250	Urological x ray studies, solution of sodium iodide for use in. One Illustration	715

Cooperation in Endocrinology as an Introduction to Research on the Morphological Constitution

By J. AUG. HAMMAR, M. D.,
Upsala, Sweden.

The editors of an American (1) medical publication recently made a statement as to organized versus individual effort in research. They said, *inter alia*, "It is doubtless true that two heads are better than one. But in our modern enthusiasm for organization we are in danger of forgetting that system and survey and encyclopedic knowledge can never supplant real thinking. Thinking is, after all, an individual performance." And later on, "A league of investigators might promote lasting benefits to the world. No one would expect it to make a scientific discovery. . . . We need not be blind to the integration in science; we must not be forgetful of the man. Genius is found in men, not in organizations."

This seems to me well put and in the main correct. I should have explicitly stated the same thing, meaning that I by no means underestimate the value of individual work and still less aim at replacing it by cooperation in the departments of endocrinology in which individual effort has already achieved such valuable scientific results, while at the same time I shall try here to call attention to certain other departments of endocrinology which are not only suitable for cooperative methods of work but, as far as I can see, can only be made accessible to science in this way.

To connect my remarks directly with what was said above with regard to scientific discoveries I may remind the reader that there are departments in science that have been for a long time so thoroughly investigated and so carefully mapped out that the prospects of making new discoveries of importance within them are not particularly great. Human anatomy is one of these departments. It is true that we can point to a case, such as Sandström's discovery of the parathyroids, published as late as 1880, thus of an organ whose vital character was shown later on, as a proof that even here a penetrating investigator can make discoveries of far-reaching importance. But we must admit that, on the whole, research work directed towards making real discoveries in this field does not seem particularly promising. And the opinion is accordingly sometimes expressed that especially gross

human morphology is a finished chapter of biology which is of greater importance nowadays as a subject of teaching than as a field of research.

I believe, however, that this point of view is not correct. It seems to start out from the assumption that the essentially analytical method of work that has hitherto been characteristic for anatomy is the only possible and correct one. It is certainly true that a separation of the body into its different components is to a certain extent so much a part of the nature of anatomy that a program of this sort may be said to be denoted by the very name of this science. It is unnecessary to express any opinion here as to the possibilities of penetrating in this analysis far beyond the point we have reached at present. In many respects the continuation of morphological analysis depends on the development of histological technic, the extension of the world observable by the microscope, and the creation of new guarantees against the confusion of preformed structure and artefacts.

It is certain that, however justified and indispensable this analytical tendency in anatomy may be, it implies a certain risk for this science as a branch of medicine and biology, namely of overlooking or neglecting the whole because of the multitude of details. There is much, however, to indicate that the time has now arrived when a synthetic direction in anatomy, taking the human organism as a unit—constitutional anatomy, if a short term is desired—may and ought to come into its own.

It is not my intention here to enter in detail into the question of what aims are to be set up in constitutional research of this sort in anatomy and what are the most suitable means at our disposal for such research. Some years ago, in a paper (2) on this question, I tried to lay down some lines of advance for it. I will only point out here that the most important condition for a synthetic tendency of this sort in anatomy is an accurate analysis, carried out according to a numerical method, of a sufficiently comprehensive and in the strictest sense normal anatomical material. I shall illustrate immediately in a more concrete way what is meant by this. But

before doing so I merely wish to point out that from this point of view human anatomy, so far from being a science that is practically complete, must rather be said to be faced with an enormous task, at present scarcely started. Not until this task is accomplished will this science be in a position to fulfill the demands made upon it by medicine, and this work can only be carried out by cooperation.

It is not improbable that the differences that appear in different individuals of the same species and that we summarize under the heading different individual constitutions, are both of a qualitative and quantitative nature. If, however, we pay attention only to such individual peculiarities as are accessible for morphological investigation, it seems as if it is only in exceptional cases that we are concerned with qualitative differences; as a rule, the variations seem to be quantitative. If, in addition, it is true—one may very well say obvious—that really scientific research on constitution cannot and ought not to do without a proper anatomical foundation, then it follows that a quantitative analysis of the different organs of the body is a fundamental condition for all scientific investigation on constitution.

For this purpose it is necessary in the first place to establish the normal range of variation so as in this way to be able to state what is normal numerically and what is pathological. Average values, with which investigators have generally been satisfied formerly, are of little importance in this respect.

Nor is it sufficient merely to establish the size of the organ—its weight. To attain a real insight into the conditions of the separate organ for the present purpose we need the most thorough morphological—numerical—analysis of it with regard to its various structural regions, if possible, right to the cellular units.

And, moreover, it must not be forgotten that the constitution is a factor that is present before and to a certain extent independent of all disease. Under these circumstances it is not in accord with sound scientific method to try to investigate constitutional conditions on the basis of cases that are complicated by disease. It is generally admitted that organs directly affected by morbid changes are not suitable as a basis for establishing the normal conditions of size and structure. On the other hand, less attention has been paid to the fact that even apparently uninjured organs belonging to persons attacked by disease are not suitable for this purpose either. As a rule, organs of this sort have been used to a great extent in working out hitherto accepted norms with regard to the conditions of size, etc., in the human organs. At most, direct lesions of the organs have been avoided in this; the indirect disturbances undergone by the organ in its capacity of a component in an organism attacked by disease have been unnoticed. Only the relatively rare cases in which a person in perfect health dies from external violence or similar causes are thus available for constitutional research in normal human anatomy.

Finally, it must not be forgotten that by establishing the range of variation in the separate organs and components of organs in a material of a nature

corresponding to the increased demands indicated here and adequate in amount for this purpose, the requirements of constitutional anatomy are by no means satisfied. Just as it is certain that all constitutional investigation is directed towards the individual considered as a unit and not the conditions of the separate organ, it is equally certain that only by paying attention to the correlation existing between the different organs or components of organs, respectively, investigated in this way in the same individual, that such investigation will come within the range of constitutional research.

Anatomical investigation does not of course afford direct information as to the functional correlation; this can at most be merely assumed on the basis of anatomical data; and to establish it science has at its disposal methods other than those offered by morphological work. But what morphology can and must establish is the correlative variability in organs and components of organs and with this the individual morphological type. The importance of this type of investigation for the race problem need only be briefly mentioned here.

For the investigation of correlative variability as for all objective comparison of biological data, the exposition in an exact numerical form of the experiences gained is an indispensable condition. From this arises the demand expressed above for numerical methods of research.

These indications ought to be enough to show that when, as must happen sooner or later, morphological investigation once sets to work on the great problem of constitution, it will have so large a field of work that what has so far been done in this department will seem but a preparation. It is also obvious that an investigation of this sort demands both so great an expenditure of time and such great systematization and uniformity of method that—to repeat what I have previously said—its accomplishment without cooperation seems inconceivable.

Nor can a program of this sort be realized except step by step. It is not only that the widening of the problems cannot be expected to take place to any great extent before the work is in progress, but the whole field of work can scarcely be submitted to investigation at once either. If there are any departments in which the need of investigation on these lines is more urgent than elsewhere it is certainly the nervous system and the endocrine system, nervous and humoral correlation being, as far as our present knowledge extends, the two ways in which coordination and cooperation between the different parts of the organism take place. Under these circumstances it is not strange if it is just these departments that promise the most abundant results from a method of working of the sort put forward here.

I shall not enter here upon the question of the investigation of the nervous system on these lines. There are indications that of late neurologists have realized more and more the importance of numerical methods in their field of work.

I can also be quite brief as to the closer application of these views to the endocrine system. I have discussed this side of the question at some detail

recently (3) and I may briefly quote something from this account to throw light on the question.

I tried in that article to show that at every disturbance of an endocrine organ, other endocrine organs too must be affected and that in other diseases these organs are probably also concerned, without its being for the present in our power to determine either the participant organs themselves or the degree to which they have been affected. To remedy this state of affairs we must, as I also pointed out, elaborate for every endocrine organ special methods, which admit of a numerical determination, with sufficient accuracy, of the material components of the organ.

These methods must in the first place be applied to a sufficiently comprehensive human material of endocrine organs. This must be normal in the strict sense indicated above if we are to attain a really wellfounded insight as to the normal range of variation; it cannot be collected except by joint efforts.

By following the attained norms we shall then be able to decide whether a value from a case of disease falls within or outside the range of the normal and in what direction an eventual displacement has occurred.

"Every organ has no doubt in this respect its own peculiar problems, a complete view of which can be obtained only by very close attention to the subject. Some of these problems, however, are so obvious that they may be indicated without further investigation.

"Thus, for instance, in the hypophysis, with accurate elimination of the connective tissue, the amount of each of the three principal portions ought to be ascertained. In the anterior portion the number of the different cell types, in the intermediate portion the number and size of the cysts with and without colloid should be approximately settled.

"In the thyroid the weight of the true parenchyma similarly with deduction of the bulk of the connective tissue is to be ascertained; again, in the parenchyma the amounts of the trabecular and adenomatous territories, respectively, should be fixed apart from the acinar portion; and in the last mentioned part the number and size of acini with and without colloid should be calculated.

"Similarly, in the parathyroid glands the true parenchyma, the trabecular and cystic tissue should be treated separately. Here, moreover, we meet with the task of approximating the relative and absolute numbers of the acidophil granulated cells.

"With regard to the pancreas, the next object should be to ascertain the quantity of the endocrine and the exocrine parenchyma, as well as to calculate the number and size of the islets of Langerhans.

"In the adrenals the quantity of the cortex and the medulla, as well as of the different zones of the cortex, requires to be expressed numerically. Perhaps it will not prove quite impracticable with morphological methods to approximate the percentage of lipoids and adrenine in the organ, which would evidently be of the greatest consequence for estimating the state of function of an individual organ.

"Concerning the sex glands, it is of special importance to ascertain the amount of endocrine tissue, in doing which for the ovaries, the corpora lutea and the so-called lutein tissues should be considered separately. To settle the number and size of the ovarian follicles lies, as Valberg (4) has shown, within the bounds of possibility even in the case of a relatively large material. To figure the state of the spermatogenesis with fair accuracy seems, at all events in the case of a human being, where the process passes on so irregularly, a difficult task; but it would, however, evidently be of great importance.

"In all these enumerations we cannot stop at apparent or relative values; the real and absolute amount of every element of tissue treated must be approximately fixed. We must not forget that a relative increase of a structural element is perfectly compatible with an absolute reduction, and vice versa."

This is briefly the program of work I put forward in the paper referred to. The organization necessary to carry it out may of course be conceived in quite different ways. To me it has seemed desirable that a central body with great authority and furnished with adequate material resources should on the one hand arrange for the appointment of the different groups of specialists who would have to work out and test suitable numerical methods for each of the endocrine organs, and on the other hand superintend the collection of the necessary material of organs and its distribution to the groups of working investigators. It is unnecessary, however, to deal at greater length with this here.

The chief purpose of these lines is merely an attempt to place the suggestion put forward in *Endocrinology* in the light of the problem of constitutional anatomical investigation in general. It seems to me exceedingly probable that sooner or later this type of research must make its way into anatomy. The sooner this is realized, the fewer obstacles in the shape of gradually accumulated incorrect ideas and conceptions will constitutional research as a whole have to overcome in the future.

It has been remarked with regard to cooperation in general in science that it puts a restraint on the valuable individual initiative. If, however, combinations of the sort suggested here are, as is of course assumed, quite voluntary, and proceed from a realization of the importance of the task and an interest in its accomplishment, I do not think that it will cause any inconveniences to be felt. We must of course not overlook the fact that this is a question of procuring primary scientific material the need of which is obvious, material which the individual investigator is then at liberty to make further use of for the needs of his own special researches. The nearest parallel to this undertaking would be a scientific voyage of exploration, where cooperation had also taken place because individual strength is insufficient to carry out the undertaking; there, too, the actual procuring of material may be of course the essential part of the common task.

One might also say that the idea of realizing a constitutional anatomy implies the relinquishing by morphology itself of some of its independence with

regard to other branches of biology. It has formerly been often strongly maintained that each science must work at its special questions and in that way best serve the whole. This may undoubtedly be justified as long as it is the question of a certain science taking entire possession of its special field. But once this has been done it would seem as if the separate biological departments must cooperate in solving the great questions common to the whole of biology. And in my opinion research on constitution, of which research on heredity forms only one, though very important, branch, and without which eugenics and racial investigation can never gain a proper scientific basis, has important

qualifications to form one day a common and unifying focus for the whole of biology. The practical importance of this question to medicine is so great that it seems to me to constitute a direct demand for it to take the lead in this matter.

The Relation Between the Adrenal Cortex and Sexual Development

By KNUD H. KRABBE, M. D.,
Copenhagen.

In the majority of endocrinological manuals and extended articles on adrenal tumors a special relation is noted between the function of the adrenal cortex and the development of the sexual organs.

Neurath (26) (1909), in his monograph on precocious puberty considers ten cases of adrenal cortex tumor described in the literature as instances of precocity in that there was development of secondary sexual characteristics. Nevertheless he remarks that in none of the cases was there found any remarkable function of the genital glands such as menstruation or ejaculation. He concludes that from clinicoanatomical findings it would seem that there existed a functional connection between the adrenal glands and the development of the secondary sexual characteristics.

Glynn (14) writes (1912): "The adrenal cortex is especially connected with growth and sex characters; adrenal hypernephromata are associated with sex abnormalities, almost invariably in children, usually in adult females before the menopause, but apparently never in adult females after the menopause or in adult males. Premature development of female sex characters in females may occur with certain ovarian tumors and of male sex characters in males with certain tumors of the adrenal cortex."

Gallais (13) concludes in his thesis of 1912: "We know that in reality the genital glands and the adrenal cortex have a common embryological origin and that identical substances belonging to the group of lipoids have been found in the adrenal cortex and the ovary. It seems therefore that in view of their action in relation to the development of the sexual characteristics, the adrenal glands supplement the ovaries, but that in these cases the adrenal glands produce sexual phenomena ordinarily produced by the interstitial testicular gland."

Schäfer (32) (1913) mentions Glynn's considerations: "The occurrence of a connection between the development of the sexual organs and that of the suprarenal cortex has been especially insisted

upon by Glynn, who is of the opinion that the cortex is concerned with the differentiation and growth of the sexual cells."

Falta (10) (1913): "By development of such hyperfunctioning cortical (adrenal) tumors in children an enormously accelerated development of the body and a premature development of the genital organs takes place."

Wiesel (34) (1913), who describes the coincidence of adrenal tumors with *pubertas præcox* and virilism, is somewhat inclined to consider the "*syndrome génitosurrénal*," as Gallais has called it, as a pluriglandular disease and agrees with Gallais in considering the connection between the adrenals and ovaries as an expression of the common development from the mesothelium.

Biedl (2) (1916) writes: "In addition to these congenital abnormalities in which unilateral neoplasms, most frequently hypernephromata of the adrenals, are especially remarkable. These in childhood are associated with an early growth of the whole body, but especially of the sexual organs, with an abundant trichosis and considerable adiposity, or as a whole, with *pubertas præcox*."

Cobb (5) (1918) does not mention the relation of the adrenals to precocious puberty but suggests that tumors of the adrenal cortex have been found in cases where the characteristics of the opposite sex have developed.

Leiner (20) (1920) describes a special adrenal cortex type of *pubertas præcox*: "When there occurs hyperplasia of the adrenals in the male, it tends to accentuated masculine precocity. When it occurs in the female it tends to change the female into the male type and to give her the secondary sexual characteristics of the male."

Lipschütz (22) (1920) mentions: "In other rather numerous cases of sexual precocity tumors of the adrenals have been mentioned, both in boys and girls."

It will be seen that opinions on the relation between the adrenal cortex and sexual development

vary; but on the whole it is suggested that there is a connection, expressed by the development of precocious puberty, in cases of adrenal cortex tumors and adrenal hypertrophy in female pseudohermaphroditism. And many authors insist on the strange fact that this puberty in girls has the character of a male puberty.

In the literature seventeen cases of adrenal tumors have been described in which symptoms of what has been considered *pubertas præcox* have been found. Cookes (7) in 1756 described a girl aged seven years, who had hair on the face and cheeks. The clitoris was large. There had been no menstruation. She died and autopsy showed a tumor over the right kidney and below the liver. In addition there was acute hydrocephalus.

Tilesius (32) in 1803 published the history of a girl aged four years. She looked old, was enormously fat and had *mammæ* and pubic hair. The hair was long and thick on the extremities and on the body. Menstruation is not mentioned. Autopsy showed a tumor, probably an adrenal tumor. Ovaries and uterus were well developed for the age. Hydrocephalus was present.

Ogle (27) and Pitman (29) (separately) in 1865 each described the case of a girl aged three years, in whom hypertrichosis developed with marked adiposity. There was no evidence of any menstrual function. The autopsy showed an adrenal tumor. Uterus and ovaries were quite small and undeveloped.

Fox (12) in 1885 mentioned a girl aged two years who was extremely fat. The whole surface of her body was remarkably hairy, especially about the genital and pubic regions. No remark is made concerning menstruation. Postmortem examination showed vulva, labia and clitoris remarkably developed. The uterus and ovaries were large. On the left side there was a tumor, probably an adrenal tumor.

Dickinson (8) in the discussion after Fox's communication said that he had seen a suprarenal tumor in a boy aged three years. He had hypertrichosis and dark skin.

Orth (28) briefly communicates (1893) the history of a girl aged four and one half years, who at the age of nine months showed pubic hair and in the last year a beard also. External genital organs were highly developed, especially the clitoris, which was like a penis. Autopsy showed an adrenal tumor. (Menstruation is not mentioned.)

Dobbertin (9) published the following case in 1900: "A girl aged fourteen months had long dense hairs on both labia and on the lower abdominal region, the side of thorax, the back and the cheeks short soft hairs. Autopsy showed a tumor of the left adrenal.

Linser (21) described in 1903 a boy aged five and one half years. When he was four years old he grew very much and was remarkably hairy. The *mons veneris* was covered with curled hairs; penis eight to nine cm. long, testicles larger than pigeon's eggs; prostate large. His body looked like that of a fifteen year old lad. Autopsy showed no macroscopical thymus. There was a large tumor of the left adrenal. Testicles did not seem to function.

M. Miller (24) (quoted by Glynn) in 1903 described a case of tumor rising from the right suprarenal gland in a girl of two years. There was luxurious growth of pubic hair. The labia majora were hypertrophied, *minoræ* projected. The clitoris measured four cm. and the prepuce could be retracted. The ovaries were enlarged.

Adams (1) (1905) published the case of a boy aged fourteen years. Puberty set in at the age of ten years, after which although he increased but little in height, he developed great muscular strength. There was growth of hair on his face. Autopsy showed tumor of the left adrenal.

Bulloch and Sequeira (4) in 1905 published the case of a girl aged eleven years who was very large. Menstruation began fifteen months previously, when she became very fat, very hairy on cheeks and lips. The *mammæ* were large, there were long axillary and pubic hairs, cyanosis and edemata. On autopsy a tumor was found connected with the left suprarenal body. Thyroid and parathyroid were hypertrophic; uterus enlarged, ovaries rather smaller than normal with fresh corpora lutea.

Ritchie gave the following communication to Bulloch and Sequeira: A girl aged four years died after osteotomy. The one suprarenal gland was the seat of a tumor (sarcoma). The sexual organs were as large as those of a developed woman. No history of menstruation, but there was an abundant development of pubic hair.

Richards (30) (1905) published the following case, communicated to him by Walker: A girl aged seven years was healthy up to the age of five years, then became very stout and a beard and pubic hair developed. Postmortem examination showed the left kidney the size of a cocoon, made up entirely of new growth. Pelvic organs healthy and normally developed for her age.

L. Guthrie and W. d'Este-Emerly (15) in 1907 described a boy aged four and three quarters years who was thirty-six inches high and for three years had had hair on face and pubes and was very obese. Autopsy showed a rounded tumor in contact with the upper and anterior surface of the kidney, possibly carcinoma. The testes contained no spermatozoa. There was no tumor of the pineal gland.

E. Glynn (14), who in 1912 wrote an important paper on the adrenal gland and sexual development, personally observed the following case: A girl aged five years became abnormally tall, fat and flabby, had a profuse growth of hair on the scalp, upper lip, pubes and back. She never menstruated. The uterus appeared to be of usual size, no hypertrophy of the clitoris or *mammæ*. Postmortem examination revealed an enormous tumor in the right lumbar region and the right suprarenal capsule could not be found. Ovaries and pituitary were normal.

Herbert French privately communicated to Glynn the following case of a girl in whom the pubic hair developed at the age of eighteen months. She was admitted to a hospital when seven years old with hypertrophic external genitals and a large swelling on the upper part of abdomen. Postmortem showed tumor of left adrenal.

Schiff (31) (1918) described a girl aged two

years with adiposity, hypertrichosis on the whole body and pubic hair, moderate beard, no axillary hairs. Chest normal; deep voice; face and neck very adipose. Genital organs were normal. Autopsy showed thymus thin and somewhat fibrous. Right adrenal gland modified to a tumor (hypernephroma). Hypophysis and pineal gland seemed slightly enlarged. Ovarian structure was normal.

Among these cases are those of four males (Dickinson, Linser, Adams and Guthrie and d'Este-Emery). Linser's case is a typical case of precocious puberty; the three other cases can probably be related to the syndrome, although the description is somewhat incomplete.

We must consider the cases in girls from a different point of view. Only in the case of Bulloch and Sequeira is it mentioned that menstruation has taken place, and in that case not before the age of ten years, the outside limit for the normal beginning of menstruation. In all the other cases menstruation is not mentioned or it has been stated to have been lacking. In describing the development of the ovaries in the Ogle-Pitman case the uterus and ovaries were said to be quite small and undeveloped. Orth mentions only the development of external genital organs. Dobbertin and French do not mention the ovaries. Richards says that the pelvic organs were normally developed for the age. Both Glynn and Schiff say that the ovarian structure is normal. Only in the case of Bulloch and Sequeira is it mentioned that corpora lutea were found.

It will be seen that these cases nearly all differ considerably from those which ordinarily have been described as cases of premature puberty. In the literature several cases have been described in which the sexual development in girls (menstruation, development of mamme and pubes) has begun in early childhood. But it is striking that in most of these cases there has been no hypertrichosis beside the pubic hairs. And in fourteen out of fifteen cases here mentioned of adrenal tumor there seems not to have been any menstruation. The difference is very important and most of the text book authors above mentioned have remarked on it without any attempt to explain it.

When we try to explain these phenomena we must first consider that the majority of cases of so-called precocious puberty in girls with adrenal tumors cannot be characterized as true *pubertas præcox*. The essential in *pubertas præcox* in girls is ovulation and menstruation and only one of these cases has shown these signs. But how can the development of pubic hair be explained?

At normal puberty axillary and pubic hair develops, but only a very few hairs on the limbs and body, although hair follicles exist. In other words, the hair follicles of the pubic region can produce more hairs than the other hair follicles. But what would happen if a generalized, pathologically abundant development of hairs, a hypertrichosis, appeared, in a child? Of course, the hypertrichosis would be most marked in the pubic region. That is the case in the above mentioned histories. In the cases of Tilesius, Fox, Dobbertin, Linser, Dickinson, Glynn and Schiff there has been a general hyper-

trichosis, in the cases of Cooke, Orth, Adams and Bulloch and Sequeira, hypertrichosis of the face. As in most of these cases we have no sign of true genital function, there is no reason to consider the development of pubic hairs as a special sexual sign, but only as a natural link in the hypertrichosis. It may be remarked that in cases in which general hypertrichosis is produced by injections of pituitrin the hypertrichosis is especially marked in the pubic region.

We will consider the development of *mammæ* in the case of Tilesius from the same point of view. The patient was extremely fat and it is commonly known that in very fat persons there is a tendency to fatty deposits in the mammary and pubic regions. In most of the other cases besides that of Bulloch and Sequeira no development of *mammæ* is mentioned, which is striking when it is considered that in the majority of the described cases of uncomplicated *pubertas præcox* in girls there have been well developed *mammæ*.

Furthermore, there are other features which must be regarded in connection with the hypertrichosis. In the histories of Fox, Orth, Miller and French the clitoris was large. In the history of Schiff the voice was deep. Generally speaking, neither the hypertrichosis nor the development of clitoris or change of voice can be considered as signs of precocious puberty in girls in whom menstruation has not appeared. Among the fifteen described cases of adrenal tumors in girls only the case of Bulloch and Sequeira can be considered as a case of *pubertas præcox*.

The symptom complex of hypertrichosis, clitoris hypertrophy and deep voice is so characteristic for the male sexual character that there is no doubt that Gallais, Glynn and Linser are correct in considering that syndrome as virilism. And this consideration is further supported by the fact, that female hermaphroditism (fetal virilism) coincides with adrenal hyperplasia (Marchand (23), Fibiger (11), Glynn (14) and virilism in adult women with adrenal tumors.

It is striking that we do not find any corresponding interrelation in men. We do not find any feminization of the boys who have adrenal cortex tumors. On the contrary, we find an accentuation of the virile elements, a phenomenon that should be considered rather as true precocious puberty.

As seen above, the relations here described have been explained from the point of view of a special connection between the adrenal cortex and the sexual organs, that the adrenal cortex produces a hormone which has influence on the development of the secondary sexual characteristics and that the tumors has caused a hypersecretion of this hormone.

We wish to make some critical remarks in opposition to this theory. First it must be said that it is not correct to conclude always from the coincidence of tumor and precocious development that the tumor causes the abnormal development. It might also be assumed that the precocious puberty or virilism could produce a disposition to the development of the tumors, or that both the tumor and the precocious puberty are expressions of a general abnormal development of the whole organism.

These views cannot be denied absolutely, although they seem less probable. It would be more easy to understand that the production of a certain chemical substance by the tumor may have a generalized effect on the organism because we see so many

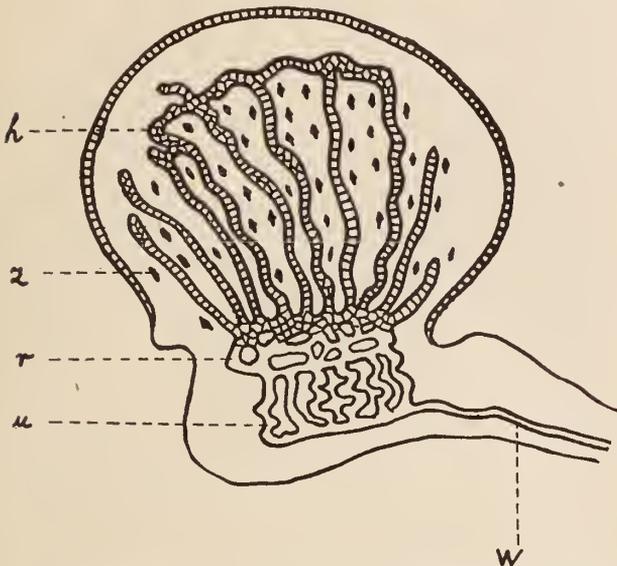

FIG. 1.—Development of the male sexual gland. (After A. Kohn.) The figure shows the pure testicular development; h, testicular channels; z, interstitial testicular cells; r, rete testis; u, midkidney; w, Wolffian channel.

analogies in the effect of thyroid, ovarian and testicular hormones, and in the hypertrichosis produced by pituitrin injections. On the other hand, we have not sufficient proof for the statement that the origin of tumors can be related to the precocious development, although a certain dysendocrine disposition may perhaps have some influence on the growth of tumors.

In consideration of the influence of the adrenals on sexual development another interrelation must be remembered. We cannot draw a conclusion of the normal function of the adrenal cells from the pathological function of the tumors. It must be remembered that we are dealing not with a simple hyperplasia, but with a development of malignant tumors, whose cells in many cases are very different from the normal adrenal cortex cells.

But apart from these questions there is one phenomenon which is striking: If the adrenal cortex really has any influence on the development of puberty, why then does hypersecretion in girls produce a male puberty and not a female? It would be difficult to explain this fact from the theory that the adrenal cortex normally has an influence on the female sexual development. It must be remembered that the influence on the sexual development which we know from the other ductless glands, such as thyroid and pituitary, is such that they are conditions for the male development in males, and the female development in females. And further, we know that although there is a retardation of puberty in cases of insufficiency of thyroid and pituitary, there is no precocious puberty in connection with tumors from these glands. Apart from the cases of tumors of the pineal body, which always have been teratomata destroying the pineal, not pineal adenomata or carcinomata, our knowledge of the

complication of tumors with *pubertas præcox* is only derived from adrenal tumors and tumors of the ovaries and testicles.

Considering all these facts, we believe that another theory could be advanced which could better explain the strange fact of adrenal cortex tumors producing a male puberty in both males and females and which could give a single point of view for the majority of cases of *pubertas præcox*: namely, hyperfunction of interstitial testicular or ovarian cells.

Marchand who has described adrenal hypertrophy in female hermaphroditism has related it to the development of ovaries and adrenals in fetal life. We will follow his example in trying to explain virilism connected with adrenal tumors in girls.

It is well known that the first seat of the adrenal cortex is developed from the mesentelium of the abdominal hollow; just beside the seat of the adrenal is the point of origin of the testicles and the ovary.

From the investigations of Laulanié (19), Janosik (17), Nagel (25) and Coert (6), whose results are accepted in the textbooks of Hertwig (16) and Broman (3) and confirmed in an important article by A. Kohn (18) as late as 1920, it is suggested that the origin of the ovary is hermaphroditic. While the testicle is developed nearly directly from the original undifferentiated stage, the ovary is passing through a stage in which the cortical part may be considered female, but the deeper medullary part is to be considered male, or testicular (Figs. 1-2); during the development the male medullary part remains rudimentary. It is this medullary testicular part that at a certain stage is intimately

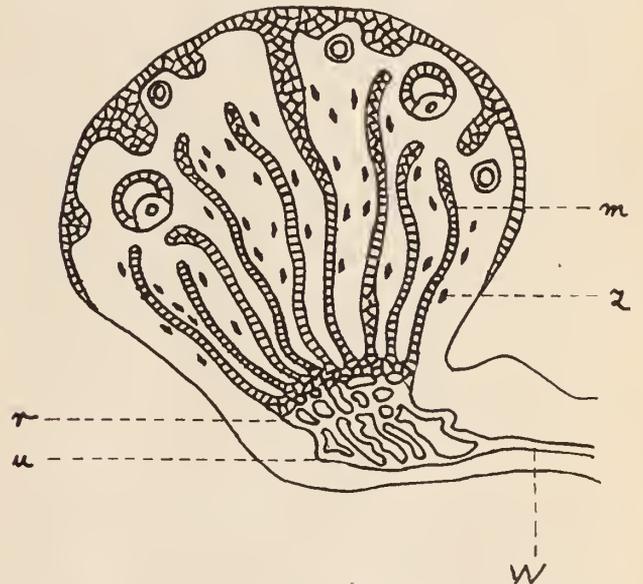

FIG. 2.—Development of the female sexual gland. (After A. Kohn.) The figure shows the bisexual development; the cortical part ovarian, the medullary part testicular; m, sexual cords (corresponding to the testicular channels); z, interstitial ovarian cells; r, corresponds to the rete testis; u, midkidney; w, Wolffian channel.

connected with the beginning stages of the adrenal cortex (Janosik).

This differentiation of development in males and females, pure testicular stage in male embryos corresponding to a hermaphroditic ovariotesticular

stage in female embryos, and the connection between the testicular part and the adrenal cortex, would then explain the difference in the onset of puberty in children with adrenal tumors, producing pure pubertas præcox in boys and male puberty signs in girls. The theory that could be based on this parallelism between fetal development and effect of tumors is the following:

The adrenal cortex tumors in the described cases are developed from an abnormally placed adrenal gland. The abnormality consists in the male part of the ovary not having been rudimentary, but absorbed by the adrenal gland and developed to a part of this. The tumor cells developed from the adrenal cortex are therefore not developed from adrenal cortex cells in an ordinary sense, but from cells which originally represented the roof of the medullary (male) part of the ovary. This relationship finds expression in the tumor cells secreting a hormone with characteristics of a testicular hormone; in other words, it produces male characteristics, causes virilism in girls.

In the four cases of precocious puberty in boys with adrenal tumors the onset of puberty is thought to have occurred in a similar manner. It is probable that in these cases the tumor is developed from an abnormally seated adrenal gland, a gland which in part is developed from the testicular foundation and whose cells therefore may produce a hormone like the testicular hormone.

In accepting this theory as plausible we conclude that the cases of adrenal tumor or adrenal hyperplasia connected with virilism or pseudohermaphroditism do not prove any special connection between the adrenals and sexual development, but that this connection may be just as well or even better explained by developments in early embryonic life.

But is such a connection indicated by other facts? Glynn says that in cases of pregnancy in some animals hypertrophy of the adrenals has been noted. But this does not prove that there is any special connection between the adrenals and sexual development, it may only be considered as an expression of the fact that in the course of pregnancy and the development of the fruit, extraordinary demands are made on the products of all the ductless glands, adrenal, thyroid and pituitary. The cases mentioned by Glynn, in which there has been atrophy of the adrenal glands with atrophy of the genital organs, do not prove any connection, since these atrophies may be considered as parallel symptoms of a pluriglandular insufficiency.

SUMMARY.

From the above considerations we draw the following conclusions: The development of pubic hair and beards in little girls with adrenal cortex tumors cannot be regarded as a special sign of precocious puberty but must be considered as a natural link in hypertrichosis. This hypertrichosis and the development of a large clitoris and transformation of the voice in little girls are only to be considered as a virilism, analogous to the virilism in adult women suffering from adrenal cortex tumors and the so called fetal virilism (female pseudohermaphroditism) in females with adrenal hyperplasia. Only in boys and in a single case of adrenal tumor in a girl aged ten years has there been found true pubertas

præcox. This theory has already been expressed partially by Glynn and Leiner.

Many authors conclude from these facts, that a special connection exists between the normal function of the adrenal cortex and the sexual organs, that a hormone from the adrenal cortex has a special influence in producing the secondary sexual characteristics. This theory does not seem to have sufficient basis; the presence of virilism in girls and women with adrenal cortex tumors, especially, cannot be explained by the suggestion that the adrenal cortex should have any influence on the normal sexual development in females.

A study of the interrelations in early fetal life will give an explanation which seems more plausible. Several investigations have shown that the ovary in its early stages is hermaphroditic. The outer cortical portion is ovarian, the inner medullary portion, testicular. This testicular part is at that stage connected with the adrenal cortex, which develops next to the genital gland from the mesentherium. In cases where adrenal cortex tumors have caused virilism, it seems most probable that the tumors have not been developed from ordinary adrenal cortex cells, but from such fetal testicular cells which have been absorbed by the adrenal cortex and developed to a sort of false adrenal cortex.

ALMINDELIG HOSPITAL.

The Problem of the Adrenals

By E. GLEY, M. D.,

Paris, France,

Professor, College of France.

Once again the adrenal problem. *Multa renascentur quæ jam ceciderunt*. It was in 1856 that the French physiologist, Brown-Séguard, discovered the fatal effect of removing the two adrenal bodies. The results of Brown-Séguard's experiments were extensively discussed; in fact, for over thirty years the results were considered doubtful and frequently as inexact. It was necessary to wait until the years 1892-1893 and 1897, when the findings were placed beyond the realm of dispute and confirmed by the researches of two other French physiologists, Abelous and Langlois, and by those of Langlois. These researches opened the pathway to the study of the mechanism of the adrenals. But in the meanwhile in England, G. Oliver and Ed. Sharply Schäfer found that the injection of adrenal extract caused an acceleration in the heart rate, an increase in the energy of muscular contractions, and an elevation of arterial pressure. Shortly afterward an American, Takamine, isolated a substance from the adrenals, adrenaline, the action of this substance being identical with that of the adrenal extracts. The presence of this substance in the venous blood of the adrenals was demonstrated, and this venous blood, when a few cubic centimetres were injected into an animal, manifested the same properties as adrenaline.

There was the same confusion regarding pathology. Little by little the pathology of the adrenals was explained by their variations in the secretion. At times too little, at times too much adrenaline was secreted into the blood stream. This idea soon extended beyond the special application so that in all cases where there was an increase of arterial pressure or, on the contrary, hypotension more or less constant, it was explained on the basis of a hyperadrenalemia or a hypoadrenalemia. All became extremely clear. We had at once the cause and the mechanism of the existing difficulties. The ideal, always looked for in medicine, a pathogenic explanation, had been attained.

I

The whole subject has again been brought into question.

Upon what data does the theory rest? The adrenals produce adrenaline since we find the substance in the parenchyma of the gland and in the venous blood issuing from it. The purpose of this substance is to maintain the arterial tonus and consequently the pressure of the blood in the arteries, because in general it maintains the tonus of the sympathetic system. Numerous experiments have shown in fact that it is a powerful stimulant of all the sympathetic nerves. A. Biedl has summed up this whole conception in a phrase: "The maintenance and regulation of a tonic innervation in the realm of the sympathetic nervous system is a function of the internal secretion of the adrenal system." (1)

Now have we the right to conclude from the pharmacodynamic action of adrenaline its physiological rôle and to identify each of these? The latter is in no way implied by the former. They are separate entities as experiments have shown.

In the first place it has been proved that the adrenals are not necessary to the maintenance of arterial tonicity: in fact, the blood pressure in the arteries during the first hours after extirpation of these glands is normal or very close to normal (as shown by the experiments of Lewandowsky, 1899; L. Camus and J. P. Langlois, 1900; Young and Lehmann, 1908; Young, 1909; R. G. Hoskins and McClure, 1912; Gley and Quinquaud, 1917). Neither is adrenaline necessary to the tonus of the sympathetic system; the experiments of Gley and Quinquaud (1916-1918) have shown, for instance, that the excitability of the splanchnic nerve is not in the least modified by double adrenalectomy or the ligation of the two lumboadrenal vein trunks.

On the other hand, it is perfectly definite that the blood in the adrenal veins contains adrenaline and that it contains more during stimulation of the splanchnic, but it does not follow from this that the substance thus liberated from the adrenal tissue acts upon the organism. To declare that a glandular product constitutes an internal secretion and as such has an effect upon the organism requires more than the mere recognition of its presence in the venous blood of the organ where it is formed; it must still be found in the blood of the left heart or in the blood of the general circulation; for it must pass into the circulation in order to reach the tissues upon which it shall act electively. Nothing proves *a priori* that the product found in the blood issuing from a gland issues into the general circulation; in fact, it might decompose or be rapidly destroyed in the mass of blood or else it might be diluted to a point where it would no longer have any effect. It is, therefore, highly necessary that it should be found in the arterial blood if we are to affirm its hormonal character.

There is a still more profound reason for this. I have maintained for a long time that the physiological destination, the purpose of the secreted product, really gives significance to a secretion. Since 1893 I have laid down this principle as the basis of a classification of glands (2). As far as the internal secretions are concerned the destination is indicated by the passing of a specific substance from the venous blood of a gland into the general blood stream and only the physiological properties of the venous blood, temporarily acquired by the blood of the aortic system, can prove it. To characterize an internal secretion, therefore, we must be able to find again in the blood of the left heart or in the arterial blood stream an active principle with properties to show its presence in this blood.

Has such investigation been carried on for adren-

ance? To be sure very minute traces of this substance have occasionally been found in the blood (Bohring and Trendelenburg, 1911); but other workers (O'Connor, Cannon and De La Paz, Dörberg) have not even detected these small amounts. The experiments which Quinquaud and myself have carried out systematically for the purpose of tracing the course of the adrenaline from the adrenal vein to the heart, and to try to find it in the blood of the left heart in a physiologically efficacious degree, have shown us that it is not to be found either in the blood of the vena cava above the hepatic vein or in the blood of the heart. In the passage from the adrenal vein to the right heart it is thus destroyed or diluted so much that it no longer reveals its properties. From these experiments we have concluded that there is no such thing as physiological adrenalemia.

This has important consequences. The function of the adrenals is not to secrete adrenaline to a degree where the product plays a physiological rôle. It is important to restudy the functions of the adrenals. From the pathological viewpoint the revision of the present ideas upon the so-called syndromes of hyperadrenalemia and hypoadrenalemia is no less urgent.

II.

The majority of the physiologists, in fact practically all, have already abandoned the theory that arterial tension depends upon the secretion of adrenaline (3); but many have not renounced the theory which is called the occasional secretion, the so-called "emergency function" of Cannon. They admit, with Cannon, that in certain conditions, under the influence of the emotions, of pain, of asphyxia, adrenaline is secreted in a sufficient quantity to pass into the blood of the general circulation and so play a physiological rôle.

And regarding asphyxia, this thesis has no support. G. N. Stewart and J. M. Rogoff (4) found that asphyxia did not increase the excretion of adrenaline, and Gley and Quinquaud (5) have demonstrated that the well known cardiovascular phenomena that are produced during asphyxia are the same before and after double adrenalectomy. On the other hand, it may be observed that all the emotions do not give rise to the reactions of excitation; there are the depressive emotions, those of sadness, which in no way accompany the phenomena of excitation in the domain of the sympathetic, and it is therefore doubtful whether all the emotions bring into active play the splanchnic system and as a result of their physical effect produce a hyperadrenalemia. But it is better to stress the significance of the experiments of Gley and Quinquaud to which I have just referred, in order to understand that the reactions dependent upon the excitation of the splanchnic remain the same after the extirpation of the adrenals; if this is so, as the emotions can evidently not work upon the adrenals except through the agency of the splanchnics, we are obliged to admit that the increase in adrenaline, found by Cannon in animals which have been frightened, has not the value which this physiologist has supposed. G. N. Stewart and J. M. Rogoff (6) observed that cats, which had one adrenal removed and the nerve

of the other adrenal cut, did not excrete any more adrenaline than did normal animals under these conditions when they were subjected to anger or fear. In spite of these facts, the theory of the "emergency function" is always strongly supported by its principal author (7).

It would take too long and this is not the place to go into the details of his criticism of the experiments of Stewart and Rogoff and of Gley and Quinquaud. To the first of these we have already replied (8). For myself I only wish to present at this time certain considerations of the subject of an experimental and also of a theoretical nature. In order to study the rôle of the adrenals, as in all other endocrine glands, one of the surest methods is evidently the complete extirpation of the organs; then one observes the phenomena on which one plans to base one's study. Many experimenters consider as equivalent to double adrenalectomy the ligation of the two venous trunks of the lumboadrenals; the operation is more simple and more rapid. Cannon (9) refers to anatomophysiological studies of Cow (10) and after a number of personal experiments maintains that it is less sure: there exists certain direct venous connections between the adrenals and the renal vein. "From these observations," says Cannon, "it is clear that conclusions based on results obtained when only the lumboadrenal veins are tied, may lead to erroneous conclusions" (11). One could, consequently, place under suspicion the experiments in which Gley and Quinquaud observed the effects of the stimulation of the splanchnic where there was no modification after the ligation of the two lumboadrenal venous trunks. But then one could probably suspect all the experiments made by this method. Now Cannon did not cease to attribute great importance to the experiments of Anrep (12), in which the vascular reaction following the stimulation of the splanchnic appeared very different before and after "the exclusion" of the adrenals. This exclusion only attained by the ligation of the adrenal veins, as well as by the ligation of a single venous trunk, on the side of the stimulated nerve. If in the experiments in which Gley and Quinquaud ligated the adrenal veins, it would be stated that nevertheless adrenaline passed into the circulation, the same supposition could be held for the experiments of Anrep. One cannot hold that one experiment is valid and the other erroneous. The principle which would cause one to be rejected should also cause the other to be laid aside. As stated in an old French proverb, *donner et recevoir ni sont*.

Another reference of the same character. In the researches of Gley and Quinquaud upon the effects of the stimulation of the splanchnic they were not only experiments made upon the ligation of the adrenal veins, but also and more frequently, experiments upon double adrenalectomy. It is this method to which we resorted most frequently; and we never relied exclusively upon the ligations, we only used it as an accessory. Therefore the majority of our experiments complied with the desideratum expressed by Cannon (13): "The only absolutely safe method is that of excluding the glands from any possible action in the body by removing them." It is not right in an examination of the ideas set forth by Gley

and Quinquaud to ignore the results of their experiments of adrenalectomy in order to take into account only their experiments of "exclusion."

The rest of this paper is of a more general order. If adrenaline plays a rôle in the production of organic reactions which accompany the emotions, for example, and characterize them physiologically, it is not understood why these reactions are limited to a certain definite territory. For adrenaline, poured into the circulation by the adrenal veins, should exercise an equal action upon the entire arterial territory. And this is precisely what does not occur. This causes us to think that it is not by a humoral mechanism (by adrenalemia) that these vascular reactions of an emotional origin are produced. It is perhaps only by a nervous mechanism. This mechanism is well known since the memorable work of Claude Bernard. It is because there exist vasomotor nerves which may cause an independent interplay that the local circulation is possible. The theory of adrenalemia is irreconcilable with the conception of local circulation. Adrenaline can only cause a common modification of the general circulation, since, once it is excreted, it is supposed to go everywhere and work in the same way on all the vessels (excepting the coronaries). The characteristic of local circulation is an independence of the general circulation, and in consequence as opposed to the general causes of the variation in the general circulation, and also their independence, one in relation to the others. May we recall the celebrated phrases of Claude Bernard? "There are, in reality, two circulations for the physiologist and for the physician: first of all the general circulation, that which Harvey made known to us: then the capillary circulation regulated by the nervous system, which acts separately for each of the organs . . ." (14). "The only general circulation, that which has been known since Harvey, does not give us any explanation of the numerous circulatory variations in the organs which follow the states of activity or rest and follow the normal or pathological states. The discovery of the local circulation and the rôle of the vasomotor nerves explains to us how each organ, each element, may have, as we may say, its independent circulation, its special nutrition, and, as a result, its function distinct from that of its neighbor" (15). Between the theories of physiological adrenalemia and the idea of local circulation, so solidly established by countless experiments, there is a contradiction.

III

From all that has preceded, it seems to me that one of the essential results of the experiments followed for many years by Gley and Quinquaud was to make known the autonomy of the splanchnic nerves, the independence of their action and the nonsubordination of this action to the secretion of adrenaline, always continues, and it is inevitable that our results should oppose the theory of emergency function. But if this theory, like that of tonus, is discarded, if the adrenals can no longer be considered the secreting organs of a substance which has a regulating effect upon the circulation, what is their function? We can come back to the earlier experiments of Abelous and Langlois relating to an antitoxic rôle of the adrenals, and, starting from

that viewpoint, make new investigations; and we might ask whether, in conformity with a view of Biedl and of Swale Vincent, the adrenal cortex—that is to say, the nonadrenogenous layer—is not essential to life, and turn our searchings in that direction. And one might conceive of still further directing hypotheses.

However this may be, once again there is the adrenal problem.

James Theory of the Emotions in Relation to the Adrenal Glands.—Charles E. Kieley (*Journal of Laboratory and Clinical Medicine*, January, 1921) carried out the therapeutic tests reported on two psychasthenics whose most prominent symptom was fear. Accepting the theory of James that we cannot experience an emotion unless we also experience the physical changes that habitually accompany it, and that of Cannon and his coworkers that the physical concomitants of fear were produced through psychic stimulation of the adrenal glands, it follows that a blocking of the adrenal hyperactivity should prevent the experience of fear. The author gave his two patients fifteen and twenty injections, respectively, of one to two c. c. of apocodeine solution, the only known substance which neutralizes adrenaline physiologically at all points, according to Biedl. This did not give the slightest relief from fear in either case. Kieley concludes that, granting that Cannon's contention in regard to the bodily effects of fear be correct, the two experiments reported indicate that an emotion can be experienced independently of the physical changes which habitually accompany it.

Evolution from Status Thymicolymphaticus

The Successive Phases and Their Treatment

By WALTER TIMME, M. D.,
New York,

Neurological Institute, New York.

Medical literature for many years has sporadically produced a variety of glimpses into status thymicolymphaticus,—from the viewpoint of the pediatricist, or the internist or some other specialist who had become interested in the condition because of its bearing in his particular field. Warnings were always uttered as to the importance of its recognition for always did its presence modify symptomatology, treatment and prognosis. But never has any real attempt been made to trace the progress of status thymicolymphaticus through the developmental years to adult life and to mark its metamorphosed characteristics and the attempt of the individual to compensate for its disturbances. In the past ten years it has been my fortune to examine many hundred cases of status thymicolymphaticus in all stages of development including adult cases, in whom the early history gave indubitable evidence of such disturbance; and as a result of a more or less comprehensive study of these cases, certain general conclusions have been drawn which I shall attempt to present, together with the facts upon which they are based.

Reviewing the general symptomatology of status thymicolymphaticus as a basis from which we shall proceed, I give hurriedly the outstanding features of this condition.

Skeleton.—Growth of skeleton is usually abnormal in that the various units are in disproportion—thorax too long for legs, and vice versa; hands and feet too long for arms and legs; bony structure usually frail and rachitic evidences are frequently present. A maxillary torus is in evidence.

Teeth.—Almost invariably there is delay in permanent dentition with prominence in size of the central incisors of the upper jaw, with comparatively small lateral incisors, and canines that have lost, or rather not acquired the fanglike shape, but resemble the incisors in that they have a cutting edge. The molars appear very late.

Joints.—The tendons about the joints are loose and hence dislocations. Subluxations are frequent together with ability to produce marked contortions of the body. The extremities are like flails and the whole skeleton is of a loosely put together character. The apparently fixed joints, such as the sacroiliac, become partially movable and hence are the seat of intense backache on fatigue. Like conditions obtain in joints of the foot, and pes planus is the result.

Skin.—The skin is soft and velvety, covered with lanugo, frequently with a marked blush on the cheeks—a typical peaches and cream complexion. The bluish vessels are easily seen through the translucent skin.

Hair.—While lanugo covers the parts which would later be provided with secondary hairy growth, yet such later growth is very late in appear-

ance. Axillary hair and pubic hair do not come in until long after the usual time for the arrival of puberty, and in the boy, beard and mustache are still later, and then very sparse. The growth on the head is, however, profuse.

* *Genital system.*—In the boy there is usually retardation in growth of the genitals, and not only this, but the growth is of undifferentiated character, so that there is a fold of the scrotum which partially or even entirely surrounds the base of the penis, resembling the labia in the female. Occasionally, one or both testicles are undescended and there may be hypospadias. In the girl, the clitoris is usually disproportionately large, the menses come on late, and are delayed and irregular.

Eyes.—The pupils are usually large and mobile, the sclera, clear bluish white, and the vessels of the fundus are extremely thin in calibre, without engorgement of the veins.

Endocrine glands.—The thyroid shows no abnormalities in size, although it is usually underfunctionating; the thymus gland is present and large, even after the twelfth year. Percussion and röntgenography will confirm this. The picture should be made at the end of a long expiration. The adrenals are invariably deficient, both as to size and chromaffin content. Indeed, the chromaffin tissues throughout the body are deficient. The pituitary gland is usually small and is encased in a sella turcica which is small and enclosed by the clinoids. This fact is of great importance in the further history. The gonads are usually small and delayed in development and in differentiation.

Vasomotor system.—The bloodvessels are of small calibre throughout the body, especially the aorta and the coronary arteries. The heart is small.

Viscera.—Frequently a tendency to splanchnoptosis. Incontinence of urine; enuresis.

Laboratory findings.—Blood: red blood cells and hemoglobin usually normal; white cells show a marked relative lymphocytosis with a low polymorphonuclear count, which at times is as low as five per cent. Usually an eosinophilia is present. Blood sugar is usually low,—.08 per cent., .060 per cent. Of importance is the carbon dioxide tension of the blood plasma, which is invariably low, minus forty-five to fifty per cent. The coagulation time is prolonged, often as long as fifteen minutes. The urine has a low specific gravity, and not infrequently shows the presence of acetone.

General observations.—From the foregoing, the symptoms exhibited by the patients are readily understood. These are fatigue and dyspnea on exertion; fainting attacks and collapse in critical situations; syncope and death in narcosis, fright and exhaustive demands. The symptoms depend upon the low chromaffin supply, the small bloodvessels,

the low blood sugar and the tendency to acidosis. Death is not due, as has been thought, to pressure of the thymus on the trachea,—or at any rate, only in the rarest cases, but is due to adrenal exhaustion. Urticaria, asthma, acidosis, enuresis, hay fever, circumscribed edema, arthritides, are all concomitants. Blood pressures are low, pulse pressure frequently down to 10 or 15 mm. The low adrenal efficiency gives a Sergeant's line on stroking the skin of the abdomen.

From the general description, no matter what your field of work may be, you will all recognize cases that have come under your notice. These patients do not all die in growth or adolescence, nor do even a large number of them. What becomes of the survivors? How do they manage to maintain themselves in the struggle for existence? Do they constantly remain a prey to their deficiencies? These questions possibly can now be answered. The development and evolution out of status by the individual's intrinsic powers of compensation and adaptability form one of the most interesting chapters in modern medicine and their recognition will enormously aid us in our power to help hitherto obscure and apparently adventitious symptoms in our patient's progress, no matter what his ailment, no matter what our speciality.

The very first consideration in the difficulty of adaptation to environment of the status case is the outstanding fatigue. This, as has been said, is due to several factors,—the adrenal insufficiency, the low blood sugar content, the low alkaline reserve and low blood and pulse pressures. If there were any possibility of overcoming these basic difficulties, a large measure of improvement would take place. But is there in the human economy any possibility of such autonomous regulation? If, for instance, splanchnic stimulation, such as is efficient in shock, were to occur, might the situation not be overcome? The stimulation of the splanchnics or the sympathetic system generally, depends for its effect largely upon an adrenalin reserve. This is wanting in the status cases. Stimulation by thyroid secretion also depends upon the sensitization of the neurovascular synapse by thyroid extract to the action of adrenalin. Again the same difficulty.

But there is one tissue which will produce the wherewithal,—independent of adrenalin—to increase blood pressure and blood sugar content, and that is the pituitary body. Does increasing activity of the gland actually occur? For a reply we must go to our case histories. We find here two groups of status cases, one, by far the larger, in which the sella turcica on x ray examination is found to be small and enclosed; and the other in which the sella is presumably normal in size and conformation. The symptomatology in the two cases is different in important particulars, and it is the former group which is of interest to us now. In the small, enclosed sella group there is always associated with the fatigue states, headache. This headache is intratemporal in situation, of intense, painful boring, or pressure, or throbbing in character, and more or less periodical in its onset. Its periodicity is menstrual or seasonal; and yet it may be produced by any factor which will stimulate the pituitary gland.

For instance, the ingestion of large quantities of carbohydrate food; cerebral hyperemia due to the intense cerebration of long continued worry or chagrin or mental effort; injections of anterior lobe pituitary extract; and similar stimulants. Just before the headaches begin, blood and pulse pressure are low in our cases, while during the headache period, both rise, as does the blood sugar content. After a year or two or three of such constantly recurring headaches, interesting data are available. These are as follows:—Blood pressure, pulse pressure and blood sugar content are all on a higher level; there has been a rapid increase of skeletal growth; and an x ray of the skull shows a sella turcica that presents erosions and thereby an enlargement of its cavity. With these facts at our disposal, I believe that the conclusion is not very far-fetched that pituitary hyperactivity has occurred and with it an amelioration of the asthenic symptoms. In other words, there has been a compensation process inaugurated automatically, which has served to overcome many of the symptoms of disability possessed by the status case. This compensatory process precedes for years, the sella turcica becoming more and more eroded, the headaches gradually becoming less and less intense and less frequent, the skeletal growth, however, going on apace. Now, other symptoms of pituitary primary activity and other glandular activity secondarily, begin to present themselves. There is gonadal growth; undescended testicles come down; secondary hairy growth begins.

The young man that has reached this period of compensation gives somewhat the following picture. His age is twenty; he is six feet or more in height; his skin, while still smooth and velvety, has begun to look more rugged. The first hairs of mustache or beard are beginning to show themselves. His pubic hair, which has been for a few years scanty and feminine in its distribution, begins to encroach on the middle line of the abdomen towards the umbilicus. His joints are loose, subluxations of the mandible or of the carpal metacarpal joints being readily produced; he has the large central incisors of the upper jaw; a torus palatinus is evident—but he is getting to be more efficient in his study and in his play, and his fatigue is diminishing. He still has headaches, sometimes very severe. It is for this symptom that he sees the oculist, or the rhinologist or the internist or the neurologist. Careful inquiry into his developmental history will elicit many symptoms of the foregoing group, and he will be recognized as being in a transitional stage of compensation from an early status thymicolymphaticus. The rapid skeletal growth and the headaches will lead the careful clinician to examine the sella and the thymic region and there the telltale marks of his progress will be seen. At once it will be recognized that the extreme height and the headaches are simply the hallmarks of a purposeful compensatory process on the part of the pituitary gland to overcome the disabling characteristics of a status thymicolymphaticus, and are not disease symptoms in themselves. This is highly important to know both for purposes of treatment and for prognosis. As we watch his progress through the years, he goes on growing,

though less and less in degree; his headaches come on only after undue fatigue or exertion; the thymic x ray shadow disappears; he may grow both mustache and beard; his blood pressure, pulse pressure, blood sugar content, coagulation time,—all approach normal, and finally even his growth ceases. We have before us, a moderate giant, six feet two inches in height, who has finally matured, physically, psychically and sexually at the thirtieth year of life instead of at the twenty-first. He will always be conscious of some limitation to his physical possibilities, but will be able to survive in competition with his fellows. In other words, he has gone to cure through spontaneous compensation. Looking back over his career, the recognition of the milestones of his progress gives us the keynote of the treatment which we may accord his less fortunate brethren in their partial or complete failure to follow his trail. That keynote is the ability of the pituitary body to become hyperactive in order to compensate for the initial adrenal insufficiency. It is incumbent upon us, therefore, to recognize those cases that continue to exhibit various degrees of thymic disturbance in their later life and, secondly, to estimate the ability of the pituitary to compensate.

These patients, besides the original structural abnormalities described in the opening chapter, exhibit especially, a, fatigue, b, low blood and pulse pressures, c, low carbon dioxide tension of the blood plasma, d, long coagulation time, e, various vagotonic stigmata, such as visceroptosis, hypermotility of stomach and intestine, urticaria and angioneurotic edema, cardiospasm, esophagospasm, high gastric acidity, angmoid attacks, attacks of syncope and so on. These symptoms are important in every field of medicine and play an extremely active part in each symptom complex. The danger lies in considering them as disease pictures in themselves and not as mere symptoms in a universal syndrome whose basis is a subinvolted thymus gland, uncompensated. The recognition of continuations of the above intruding themselves into our patient's complaints will make for more thorough diagnoses and more thorough basic rational treatment.

As we have seen that automatic compensation of a thymic state depends upon potential hyperactivity of the pituitary body, we must estimate this possibility by the very means as yet in our power, namely, the size of the sella turcica, and its freedom from complete enclosure. As before stated, the two large groups of our cases are separated on a basis of sella turcica conditions; the small enclosed sella giving rise to the pressure symptoms, with headache, growth, and gradual amelioration of the symptoms provided the sella become eroded and enlarged.

The normal sella group have at most only intratemporal pressure symptoms of a mild degree, but growth has been rapid and blood pressure, pulse pressure and blood sugar have gradually risen, and with this rise, a general improvement in the asthenia has taken place, and in a comparatively short time, our patient is normal and no longer interests us.

Furthermore, with a large, roomy sella from the very beginning, compensation may occur without any symptoms whatever and the case never comes to observation.

There is still another possibility, namely, that the small, enclosed sella will resist enlargement or that the pressure exerted within it is never sufficient to produce such enlargement. In either case, an inefficient pituitary activity leaves the patient at the mercy of his thymic subinvolution. At this point our therapy becomes effective.

Having decided then that our case presents the earmarks of an early thymic subinvolution, it is our function next to determine the phase of compensation at which the patient has arrived. An x ray examination of the chest and skull will help. The chest may still give evidence of a persistent thymus gland, although the absence of a thymic shadow is not necessarily proof of the absence of the thymus. The skull, however, will show a sella turcica of one of the following types:

- a, small enclosed, no erosions.
- b, small enclosed, with erosions.
- c, medium size, smooth wall, open between clinoids.
- d, medium size, eroded walls, or clinoids, or both.
- e, enlarged with evidences of extensive erosions.

Type a is of the noncompensating group of cases. This group requires constant treatment, probably throughout life.

Type b shows beginning compensatory enlargement, judged by the eroded walls of the sella, and requires treatment for the compensatory effort.

Type c is a normal sella which may or may not enclose a hyperactive gland, and in which treatment will depend upon the efficiency of the hyperactivity.

Type d is of normal size but has been made so by constant pressure, as witnessed by the marked erosions. In this group of cases there is usually a history of long continued, severe headache of migrainous character, intratemporal in situation and frequently of ophthalmoplegic type. This ophthalmoplegia depends upon the lateral encroachment of the pituitary body to the cavernous sinus. The sinus conveys the third, fourth, sixth, and ophthalmic division of the fifth cranial nerve within its walls and pressure upon it, of the pituitary body will involve one or even all of these structures. Hence the symptomatology will include, during the headache, diplopia, strabismus, ptosis, pupillary abnormalities and so on. The radiologist will often report such a sella turcica as normal in size, without suggesting erosion, not recognizing that the normality in size is simply a transitional state from small to large. This is of importance to recognize.

Type e is the final state of a sella turcica in cases in which complete compensation may have taken place with gigantism, or acromegalic features, but with normal blood pressures and normal blood chemistry.

By means of these examinations, together with the patient's symptomatology, we can arrive at some conclusion as to his present whereabouts, in the progress to complete compensation. I divide the entire period of evolution into periods; first, the actual status of origin; second, the period of beginning compensation with beginning rapid growth, headaches and symptoms, both physical and psychological of an underdeveloped pituitary body; third, the period of enlargement of the sella turcica with a gradually decreasing fatigue, decreasing headaches, and a slowing down of growth; and fourth,

the terminal period, in which the condition becomes fully compensated, with cessation of growth and of headache, and much moderation of fatigue.

The difficulties arising in each of these stages have been only lightly touched upon in the foregoing; but each period has a host of major and minor attributes that only a long experience will make familiar. I would like to mention here chiefly the mental disturbances with their concomitant behavioristic anomalies. During the second and third stages, namely, those of continuing compensation, the individual contending with his headaches and fatigue cannot give proper thought nor consecutive attention to the problems before him. As a result, he falls behind his more fortunate brothers in school and college and becomes backward in intellectual development. Realizing his inability to compete with them, he likewise separates himself from their company and their games, and becomes shut in. This leads to various psychic phenomena, with morbid thoughts and fears and a more or less depressive state supervenes. One curious condition which we have often seen in our patients at this stage, in those with small enclosed sellæ turcicæ, is a lack of inhibition which manifests itself in a variety of ways. They do and say the first thing their environment impels them to, without allowing judgment to enter until too late. Thus many of our patients are pathological liars, kleptomaniacs, moral inferiors and drug habitués. They always avoid obstacles by the means nearest at hand, and never by any chance either endeavor to overcome them, or make early provision against them.

When compensation is complete, however, or treatment is instituted early enough, many of them are improved in these regards as well as in the matter of their physical disabilities. A certain number of patients never compensate, the sella remains small and enclosed, and their lot is constant observation and treatment.

So that we see in the evolution from status thymicolymphaticus a series of stages involving a symptomatology which encroaches upon all fields of medicine from surgery to psychiatry. The tangential points are the ones that all of us must watch for, and once found and recognized, are the keystones to a complete understanding of the patient.

A knowledge of the dynamic process going on in our patients, and of the goal that the autonomic procedure is striving to attain, is the groundwork of our treatment. To recapitulate, the pituitary must do additional work to increase blood sugar and blood pressure, for the adrenals are inefficient. Then the active thymus must be inhibited. The lack of differentiation in structure and gonadal characteristics of the thymus cases may be partially overcome by the administration of small doses of thyroid gland and of iodine. This is based upon recent investigations on the positive effect of thyroid gland and iodine upon differentiation in lower forms of life. The thyroid dosage should be low, one tenth grain daily; or of thyroxin, Kendall's product, a half milligram daily or on alternate days only. Iodine in one or two drop doses, well diluted, or in the form of sodium iodide, grains five, on alternate days will suffice. If the thymus remains large, it

should be x rayed at periodical intervals, depending upon the urgency of the case. But the chief treatment must be directed to increasing the pituitary supply. In those cases in which the sella shows much erosion with gradually increasing efficiency on the part of the patient and a diminution of headache, no treatment at all is indicated. But where the effect of compensation is not apparent, the fatigue and headache persist, then pituitary medication is essential.

The correct administration of this product is extremely difficult to outline, for there are certain times when it increases the headache in individuals. and frequently, if continued without intermission, a gradually diminishing effect is seen. Personally, I begin with a quarter grain capsule of the whole gland, given once daily on an empty stomach. Frequently, after three or four days, the patient complains of pressure in the head, intratemporally. I then omit giving it for a day or more, and begin again. In girls, it is usually omitted a few days before the menstrual period, for it increased the headache usually present at that time in them. Gradually, with this small dose, conditions improve. If not, the amount is slowly increased, but given intermittently as before. Rarely do I exceed a daily dose of three or four grains. The patients, before very long, begin to feel the good effects of this treatment and become expert in their own cases, so that they can tell when and how much glandular extract to take. Stimulants of the sympathetic nervous system are efficient in tiding over especially severe periods of weakness. These include coffee, atropine in small doses, and alcohol in small doses. One might think that suprarenal gland extract or adrenalin would be of good effect. The former sometimes is of service in conjunction with pituitary feeding, but adrenalin usually is not. After ceasing the administration of adrenalin by mouth, the blood pressure usually falls below its former height. And when given hypodermically, the reaction is frequently bad and leads occasionally to syncope. Its effect is much like that of cocaine in these cases,—rapid adrenal exhaustion takes place due to intense stimulation of the splanchnics. Administration of alkalis—carbonate or bicarbonate of soda several times daily is of the greatest service in combating the low alkaline reserve.

Apart from active treatment, it is necessary to enjoin certain measures on our patients. They should not subject themselves to, 1, exercise, especially of a competitive nature, except in extreme moderation; 2, cold water bathing; 3, excessive ingestion of carbohydrates; 4, too intense application to any one task for a considerable period; 5, worry, anger or emotional strain; 6, narcosis, especially chloroform, cocaine or its derivatives.

They should have air, sunshine, and much rest. Food should be taken frequently in moderate quantities. Adjuvants of all kinds will readily suggest themselves in the conduct of any one case and of course the special treatment involving any particular organ of little resistance must be carried out.¹

¹ Case histories belonging to the evolutionary stages may be found in *A New Pluriglandular Compensatory Syndrome* by Walter Timme M. D., in *Endocrinology*, July-September, 1918, Volume 2.

Endocrine Dyscrasias in the Production of Epileptic States*

By JOSHUA H. LEINER, M. D.,
New York,

Adjunct Attending Neurologist, Lebanon Hospital; Assistant, Neurological Clinic, Mt. Sinai Hospital.

It can be said almost axiomatically that when the definition of the etiology of a disease requires more than three words, its true causation is unknown. This applies with equal force to the epilepsies. The etiology varies from an attempt at a fixed pathology involving the cornu ammonis and other anatomical structures, down the list to the failure of adjustment of the patients' deep instinctive levels.

Tramer (1), who has studied the structure of the brain intensively, has recently shown that there is no true pathological condition peculiar to this disease. Clark (2), who has approached the study of the epilepsies from the clinical psychological side, has not been capable of distinguishing an organic epileptic attack from one of psychogenic origin.

The mechanism of epilepsy has been definitely shown through the work of Sherrington (3) on cerebrate and decerebrate animals, also Prus (4), Hering (4), Nino Samiajo (4), Rothmann (5), Gowers (6), and others. There is, however, no unanimity of opinion as to the force that provokes this mechanism and incites its periodical manifestation. To attempt explanations of the various conceptions is beyond the scope of this paper. However, there are several avenues by which the subject may be approached from a practical viewpoint. These eventually converge and coalesce to a single point, i. e., the endocrine system.

First, at the level of the vegetative nervous system; second, through the finer biochemical cellular metabolism (calcium, phosphorus, sodium and magnesium), and third, at the level of dyscrinism.

VEGETATIVE NERVOUS SYSTEM.

The physiological conception or rather pathological physiological existence of sympatheticotonic and vagotonic states as disease entities, being offspring of the vegetative nervous system, showing definite pharmacodynamic partitions, paralleling to a great extent the activities either paramount to, or subservient of, the endocrinous glands, opens up a veritable *sesame* regarding the concept and mechanism of this disease.

The Vienna school of Eppinger (7), Hess, and others have somewhat modified their views, and they are not as dogmatic as they were in their original schema. I must confess that I have been unable to find a pure case of either type described, despite the careful study of hundreds of cases coming under observation.

The control of the vasomotor system by the vegetative nervous system is an acknowledged fact, but that the epileptic attacks are induced as a result of a pure physiological vasomotor constriction cannot be accepted. Attacks of unconsciousness often simulating the epilepsies as in Ménière's disease (with its attending vertigo, mentioned by Gowers) (6), and the attacks of syncope, do not show, in the

main, any other points of contact. The syncopal attack shows an enfeeblement of the pulse and a feeling of faintness preceding unconsciousness, whereas in the epilepsies the pulse is normal, the face is cyanotic instead of pale, and unconsciousness comes on suddenly. The onset of the attack is also different.

One Japanese observer who compressed both carotids of epileptic patients produced typical attacks of epilepsy in a number of cases, but none were induced in normal individuals or in patients suffering from other diseases, showing that some other factors must be present in epilepsy.

It is interesting to note in this connection that Rossolime (8) has placed the vasomotor control as far up as in the frontal lobes, while Bechterew (8) placed it in the internal capsule, the caudate nucleus and the thalamus. Sajous (4) has pointed out that the superior cervical ganglion which has three nerve bundles sends two to the eye and its muscles, and the third accompanies the internal carotid which finally has been traced to the pituitary. Of still further interest, the peripheral circulation has recently been found to be capable of assuming an autonomous function (venules and capillaries) either through its nervous mechanism or directly through chemical factors (9). This in part may explain the various types of cyanosis and local patchy anemias in the epilepsies, phenomena seemingly contradictory and heretofore not solved.

So we can summarize by stating that while the vegetative system through its vasomotor mechanism is capable of producing unconscious states, it is incapable of producing genuine epilepsy (for it presupposes previous altered cellular metabolism) which exhibits itself both in character of attack and periodicity.

CELLULAR METABOLISM.

Gowers's (6) realization that epilepsy is due to some chemical affecting the nerve cells showed his profound grasp of this puzzling disease. In approaching the epilepsies from the level of perverted neurocellular metabolism, one can dip into a broad field of conjecture and theory. However, there are a few outstanding facts worth noting. Most glands of internal secretion control calcium metabolism, particularly the parathyroids, the pituitary, thymus, and adrenals. In tetania parathyreopriva, calcium metabolism is profoundly disturbed in the tissues. The works of Ott (10), Biedl (22), MacCallum and Vögtlin (22) have shown that the exhibition of calcium salts stops the tetany and convulsions resulting from parathyroid extirpation. In the absence of the parathyroids, these convulsions ensue. Here unquestionably perverted cell metabolism arises and as Schäfer (10) states, "The parathyroids yield to the blood a special autocoid—presumably of a chaloneic or restraining nature—which tends to prevent overex-

*Read before the Alumni Society of Lebanon Hospital, February 8, 1921.

citation, or discharge of nerve cells." Paton (10) and his coworkers believe it is due to guanidin. Sabbatini (11) states that the application of sodium makes the brain more irritable and excitable; these properties being lessened by the application of calcium. Substances that precipitate calcium heighten the excitability of the nerves. It may be due to this that a salt free diet decreases the number of attacks in an epileptic.

Prior and Jones (11) cite three cases showing evidence of parathyroid convulsions in which the patients were benefited by the administration of parathyroid substance. These workers have done the best work up to the present time on the calcium metabolism relative to the epilepsies, particularly on the urine and blood. Their investigations show that before an attack there is an increase of calcium in the urine and a diminution of excreted phosphates. After the attack an increase of both phosphates and chlorides is found. Again, the alkalinity of the blood in epileptics is diminished and it falls still lower preceding the attacks; this is accompanied by a concomitant fall in the leucocyte count. After the attack there is an increase of leucocytes and a rise in the calcium and alkalinity of the blood. Barr (11) has shown that the administration of phosphoric acid increased the frequency of attacks in epileptics. These investigators conclude that the calcium metabolism is the common ground upon which all glandular function is concerned in the epilepsies and therefore is the cause of epilepsy. This, in my opinion, is not the answer to the whole riddle. While a great number believe with Gowers that there is a chemical basis, there is a more subtle change in the cellular metabolism than is stated in the theory advanced by these workers. The stage of preparenchymatous change in all tissues is always first attended by finer biochemical changes of metabolism. The vegetative system is the intermediary attendant upon all these metabolic changes, whether nervous or otherwise. This has been shown by the study of visceral neurology. This is illustrated by the fixed pathological findings present in Wilson's disease, cirrhotic liver and lenticular degeneration, in fact the entire group of dystonia lenticularis as advocated by Thomalla.

ENDOCRINE DYSCRASIAS.

Von Monokow (12) states, in speaking of the embryological endocrine activity, "the endocrine system is well developed at a period of fetal life when the essential structures of the brain are lying in deep slumber." Just as the endocrines are directive in our embryological phase of existence, so, too, in our afterlife the endocrines make us what we are.

The functional activities of the endocrines are interrélated, and will often show symptoms not referable to the gland primarily affected. This must be taken into consideration in attempting to elucidate various phenomena as they arise in the dyscrasias.

PITUITARY GLAND.

Deficiency of the pituitary resulting in epileptic states is an established clinical fact. Any lesion perverting or causing a diminution of the secretion of this gland, or preventing it from entering the third ventricle through the infundibulum will eventually induce states of epilepsy. This has been pointed out

repeatedly, particularly by Cushing. Whether the secretion is perverted or only arises from the posterior lobe is not essential to our subject, but it is interesting to note that Blair Bell (13) who has done considerable work, both experimental and clinical, on the pituitary, believes that the active chromophile cells of the anterior lobe show no great difference from the cells of the pars intermedia (which he characterizes as *proinfundibulum*) and that the secretion acquires its pressor principle after it enters the pars nervosa. The substance so secreted is believed to affect the cortical cellular metabolism and produce a state of stability. It is most likely oxidative in nature. Victor Horsley has shown experimentally that the cortex in dogs deprived of their pituitary glands was far more sensitive to electrical stimulation. It would not be amiss to mention the intimate relationship existing between the superior cervical ganglion by way of the internal carotid and the pituitary. It is most illuminating when one considers its interrelationship with the chromaffine system and throws considerable light in the production of the epilepsies induced supposedly by the adrenals. I have in mind particularly the experimental work of Benedek (14), Schaller (15), and others, and the clinical interpretations of Tracy (15). They point out the altered cortical cellular metabolism due to an altered or diminished pituitary secretion, which in turn enters into the production of epileptic states.

Tucker (26) found that of two hundred cases of epilepsy, 31.5 per cent. revealed some evidence of pituitary implication, and of these, excluding all other diseases, fourteen per cent. showed pure pituitary types. Munsen (16) found at the Craig Colony that the gland was somewhat smaller in size and weighed less, as compared to the normal. Uncinate attacks due to temporosphenoidal irritation have been mentioned by Cushing (17). The following case is predominantly pituitary in origin.

CASE I.—E. G., five and a half years old, female, an exceedingly bright child, had attacks of both petit and grande mal. The first attack came at the age of four, while the child was at a summer resort. It was stated that she fell to the ground. A year later another attack occurred, and thereafter they came every four or five weeks. Later they occurred twice a week. The past history of the child revealed nothing referable to birth, development or past illness. There was a history of fainting spells in the father's sister.

Examination showed a child somewhat short for her age. The head showed some frontal bulging. The teeth were small and in a bad condition. A distinct Sergent's white line was elicited. I thought there was a slight weakness in the right upper and lower extremity. Aside from this nothing was found neurologically. Her optic discs were somewhat hyperemic. The exhibition of luminal and small doses of thyroid apparently increased the attacks. An x ray of the skull revealed a somewhat enlarged sella, and in addition an irregular floor. Whole gland of pituitary was given with benefit. Her attacks stopped, her appetite returned, she became stronger and less sleepy, and the Sergent's line became feebler. This child undoubtedly had an

adenomatous enlargement. Whether the first fall had anything to do with it, one cannot tell, although Tucker (26) speaks of these cases as giving an early history of a fall. The Sergent's line revealing the hypoadrenia shows the exhaustion of the pressor principle of the pituitary, which then called on the adrenals for aid, with the latter becoming finally exhausted. The faulty metabolism in shown in the sleepy state, lack of vigor and loss of appetite. This may also have been due to other glands indirectly affected.

THYROID.

This gland deals more directly with cellular metabolism than any other gland of internal secretion. A lack of function leads to sluggishness throughout the body. This is visible in the subcutaneous infiltration of the skin and the intestinal walls, leading to constipation, and the autointoxication and a decreased alkalinity of the body in the epilepsies, as pointed out by Prior and Jones. In fact one of the striking clinical symptoms to contend with in epilepsy is the constant constipation.

Epilepsy has been long associated with athyroidal states as myxedema, cretinoid idiocy and simple goitres. Hertoghe (18) and Levi and Rothchild (19) have repeatedly shown the association of epilepsy with thyroid disturbance. Thyroid has been used empirically for a long time in the treatment of epilepsy with beneficial results. Falta (20), Gowers (6), Claude and Schmergeld (21), and Prior and Jones have established the association of the thyroid and epilepsy. Gowers found enlarged thyroids, particularly in females in the first half of life; often associated with exophthalmos and a rapid pulse. Claude and Schmergeld found both areas of sclerosis and hypertrophy in the gland. Prior and Jones found both active glands and quiescent ones in epilepsy. The mechanism in the thyrotoxic type is caused indirectly through the sympathetic adrenopituitary cycle, thus showing that epilepsy is not a disease entity, but a symptomatic disease.

The following case is of interest because of a probable thyroparathyroid implication and the association with eclampsia.

CASE II.—F. S., female, aged twenty-five, married. Her only pregnancy resulted in the birth of a seven and a half months' child. This was preceded by a convulsive fit. The patient states that she has had kidney trouble since this period. I once witnessed part of one of her attacks. Her pupils were dilated and did not react to light. Her knee jerks were exaggerated, but there was no clonus or Babinski present. After the attack amnesia and mental confusion with headache were present.

Examination showed a dark complexioned, short young woman, with hirsuties on both legs and chest. The teeth were poor, and a hard sclerosed mass was found in the neck, occupying the right lobe of the thyroid. It was the size of a pigeon's egg. The blood pressure was 130/75. The urine showed albumin and hyaline casts. She complained of feeling cold constantly, especially cold hands and feet. She complained that her hair had been falling out. Under dietetic treatment and parathyroid extract her attacks diminished. Her urine still showed some albumin and a few hyaline casts. She was later

given thyroid extract, her albumin decreased, her hair stopped falling out, the diet was increased to include nitrogenous foods, and her epileptic attacks ceased.

This case is of interest in that the relationship of nephritis to parathyroidectomy and its effect on these glands was pointed out by Massaglia (22). The symptoms point to a thyroid, parathyroid dyscrasia. The falling hair, nephritis, vasomotor disturbance, poor teeth and her probable eclampsia at seven and a half months and finally her epileptic attacks improving under the above treatment makes this appear to be a thyroid parathyroid involvement. The right lobe of the thyroid and both parathyroids were probably involved.

Prior and Jones (11) report three cases of epilepsy in their series that showed benefit under parathyroid therapy.

THYMUS.

The following two cases of epilepsy showed both major and minor attacks which could be classed under the status thymicolymphatic type. The patients showed marked improvement following the exhibition of glands containing the pressor principle (pituitary and adrenal). These are the cases that approach the thymico, pituitary, adrenal type of Timme (23). They also come under the hypoplastic type of cases (status thymicolymphaticus of Bartels). They are distinctly vagotonic and bear out the endocrinous metabolic origin of epilepsy (the vegetative system acting as the intermediary), more so than any of the others. Here we find a small cardiovascular apparatus and other conditions showing the physical inadequacy of these patients. Douglas Symmers (24) found on autopsy that many cases of status lymphaticus were epileptics and advised incidentally x ray therapy applied to the thymus to counteract lymphoid tissue proliferation.

CASE III.—A. B., fifteen and a half years old, male high school student, had major and minor epileptic attacks for the past four years. He was born by a low forceps delivery. In early childhood he perspired profusely and was continually subject to colds. At six years of age he had an attack of asthma. Onanism was admitted, being practised once a week.

Examination: Eyes reacted to light and convergence, no extraocular disturbance, the fundi were negative. The color fields of both eyes were contracted particularly to green; the right eye showed a greater contraction to red than the left. The knee jerks, ankle jerks, and abdominal reflexes were present and normal. A suprapatellar reflex was elicited. No ankle clonus or Babinski was present. An intense Sergent's white line was present. His musculature was well developed. The arms were long, reaching within six inches of his patella. A female distribution of pubic hair was present. The pulse was 62, blood pressure 104/54.

Laboratory findings: Blood examination—Red blood cells, 3,900,000; hemoglobin, 80 per cent.; color index, one; leucocytes, 8,400; polynuclear neutrophiles, 54 per cent.; lymphocytes, 30 per cent.; large mononuclear lymphocytes, 9 per cent.;

eosinophiles, 7 per cent.; basophiles, 0; abnormal forms, 0.

Blood chemistry: Blood sugar, 0.095 per cent.; carbon dioxide, 58 per cent. per volume; coagulation time, 7 minutes 40 seconds; blood Wassermann negative; x ray of skull showed abnormally thickened and clubbed posterior clinoids.

Treatment: The patient was placed under anterior pituitary lobe fresh gland treatment, but with no apparent benefit. Thyroid feeding gave him some benefit. However, the posterior pituitary, or, rather, the whole gland which includes the posterior pituitary plus a small amount of the whole adrenal gland, gave the best results. His attacks gradually diminished in severity until he only had a mild attack of petit mal once a week.

Three members of his family were endocrinopathic. The father was the red checked, beardless type, who showed a female suprapubic hair distribution and no hair in the axilla. A further questioning revealed minor qualities of a vagotonic individual. The mother was only four feet six inches in height, with a large trunk and short lower extremities. She weighed 162 pounds. She had headaches accompanied by vomiting. Her mother (the boy's grandmother) also suffered from headaches. The grandfather died from asthma at sixty. The grandparents were both short in stature. The patient's mother stated that she commenced to gain weight rapidly after her marriage and that her hair fell out periodically. Examination showed that her pupils reacted to light and accommodation and that there was a slight internal strabismus of both eyes. Hirsuties was present on her upper lip, her hands were pudgy and her eyebrows thin, especially at the outer third.

A brother aged nine was fifty-four inches in height and had a bilateral arm length of fifty-three inches. Mouth: His lateral incisors were less than half the size of his central incisors and the palate was highly arched. His eyebrows showed no hair or very fine lanugo. He had a dolichocephalic head. Sergeant's white line was present.

SUMMARY.

This boy had an endocrinopathic ancestry from both sides, the father a status type and the mother and grandparents dyspituitary in type. His infantile history showed him to be a vagotonic individual, i. e., the profuse sweatings and asthma at six. At present he showed anthropoid arms, a Sergeant's white line, low blood pressure, high lymphocyte count, and an eosinophilia of seven per cent., all pointing to a status type plus vagotonia. When last seen he had an occasional attack of petit mal.

CASE IV.—The following case referred to me also showed a status thymicolymphaticus type plus vagotonia. The attacks began with convulsions at the age of two. He had one attack every three or four weeks for a few months and then they ceased. His present attacks began at the age of fourteen, and at fifteen he had several more attacks. They then became more frequent, often occurring twice daily during the past two years. The type of the attack showed them to be regular major attacks.

Examination: The eyes were normal, except the right fundus which showed a slight temporal pallor.

Otherwise his neurological examination was negative. He revealed anthropoid arms, female distribution of hair over the pubis, no hair on face or in the axilla. A Sergeant's white line was present, but not marked. The blood pressure was 110/72 and the pulse 70. An x ray of the skull showed the sella to be somewhat deeper on the interior part of the floor. His posterior clinoids were indistinct. The epiphysis and diaphysis were separated in the radius. He was placed on anterior pituitary together with thyroid with excellent results. His physician and also his brother, who have observed him, state that he is a different boy now. He takes an active interest in boyish sports, is much stronger, does not tire easily, is much brighter and has lost the constipation from which he suffered for many years. When last heard from, he had had no attacks for several months, and was feeling well.

GONADAL TYPE.

The following case showed the implication of the genital glands in the production of epilepsy. This is a case of eunuchoidism:

CASE V.—J. H., male, aged thirty-five, married, no children. The family history showed that both parents were tall, as well as his brothers and sisters. His chief complaint was headache for the past four years, mostly of a bitemporal nature, and increasing in severity. He volunteered the information that his eyesight was becoming more dim. He had several attacks, the last one on November 7, 1920, of which he still showed evidence on his forehead, the result of his last fall.

Examination showed him to be six feet two inches in height. He had a smooth skin of female texture, a microcephalic head, a face of mongolian type, with large prominent malar bones, eyes almond shaped, hair scant on pubis and of female distribution, no hair in the axilla and little on the face. His penis was the size of a twelve year old child's, and the testis the size of a bean. His breasts were enlarged. His pupils reacted to light and accommodation. There was no ocular muscle disturbance. Slight weakness of the right side of the face; upper jaw slightly prognathous; mouth showed a highly arched palate; uvula and tongue in median line; teeth of upper jaw overlapping the lower ones considerably. The central incisors were prominent, but the lateral incisors were not smaller. The right lateral incisor was canine in shape. The lower incisors were smaller. Reflexes of the right upper extremity were increased as well as the right knee and ankle jerk. An abortive Babinski, but a positive Oppenheim was present on the right side. An x ray of the skull showed the bones to be thickened. A pineal shadow was present. An area of rarefaction was visible in the frontal bone. The sella was somewhat larger than normal, the floor slightly irregular, and it was entirely bridged over by the clinoids. This patient was placed upon pituitary with excellent results. He is entirely free from his headaches and attacks of epilepsy.

That the interference with the gonadal secretion can produce epilepsy is an old conception, particularly when the menses in the female cease. Prior and Jones (11) found fibroses of the ovaries, together with atrophy of the interstitial cells. They

found that out of forty epileptics only three showed regular menstruation. Ashe reports that three cases under his care with ovarian dyscrinism, having epilepsy, were cured either by feeding ovarian gland or by injection of the extract of this gland.

That this patient (Case V) showed an enlarged pituitary is evident, and it was due to the atrophy of his testes. That the removal of the testes leads to enlargement of the hypophyses was first shown by Fichera (22) in 1906, in his experimental work on animals. He diminished its size by injecting testicular extract. It is also interesting that Abt (22) and Schüller (22) ascribes mongolism to the absence of this gland. This patient showed some traits of this character. He also showed evidence of a pyramidal tract lesion.

CONCLUSIONS.

From what has been shown in this paper it is evident that the endocrines are the dominant factors in the production of the epilepsies.

The vegetative nervous system is the intermediary between the glands and the biochemistry of the cells of the body. In the treatment of the epilepsies, Jacobi, and particularly Oppenheim, had great faith in atropine as a therapeutic measure when the bromides failed them.

Let us hope that the future will throw still further light upon the relationship of the endocrines to this affliction, so that mankind will be more fully capable of combating every case that arises, or, better, by judicious therapy prevent its occurrence.

The Endocrines in Everyday Practice*

By CHARLES E. DE M. SAJOUS, M. D., LL.D., Sc. D.,
Philadelphia,

Professor of Applied Endocrinology, University of Pennsylvania Graduate Medical School.

You are probably not aware of the fact that therapeutic nihilism has grown to such an extent that many of our most prominent medical schools are now giving the treatment of disease by drugs but scant attention. The fundamental cause of this attitude is but a normal result of the incompatibility of therapeutics with the trend of modern knowledge. Most remedies are used empirically today as they were fifty years ago; most textbooks of practice continue to refer to a remedy or a combination of drugs as serviceable or useful or as having been found efficacious by so-and-so, etc. Excepting perhaps in the case of our few specifics, no attempt is made to explain the mode of action of a given drug upon the pathological process it is intended to antagonize. This does not mean, in keeping with the

therapeutic nihilist's belief, that therapeutics does not subserve a very useful purpose; far from it. It does mean, however, that its practice being out of harmony with scientific progress in all other branches of medical knowledge, it is being dropped by the wayside as a relic of charlatanism, a haphazard—though sincere—attempt to relieve or cure, in which precision plays but little if any part. Professor Lewellys F. Barker over two decades ago stated that "pharmacotherapy was moribund." Its increasing elimination from medical schools suggests that its interment has begun.

Pharmacology, meaning by the term the experimental study of the action of drugs, does not seem to be extricating therapeutics from its downward course. Although practitioners are in part to blame for this owing to the acquired habit of using drugs empirically, it is a question whether willingness to

*Lecture delivered by invitation before the Bucks County Medical Society, at Bristol, Pa., May 18, 1921.

avail themselves of the pharmacological work published would aid them seriously in establishing their treatment of disease on a more scientific footing. Two reasons, among many which could be adduced, tend to sustain this conclusion: 1, the experimental work is done almost exclusively in *normal* animals, and thus conveys but a vague idea of the effects of the drug being studied in disease; 2, experiments in normal animals obviously entail, through the absence of a morbid process, the exclusion of the kind of study which the practitioner most needs: that bearing upon the *cure* of disease. Briefly, while pharmacologists and biochemists contribute much to our knowledge and our pharmaceutical armamentarium, we miss in their work the very soul of our aims: a knowledge of the manner in which remedies antagonize disease and defeat its death-dealing effects.

Hence the fact that we possess so few specifics. Frank Billings in his Presidential Address at the 1903 meeting of the American Medical Association, declared that "drugs with the exception of quinine in malaria and mercury in syphilis, are valueless as cures." The fact that but two agents have been added to the list during the eighteen years that have elapsed since this declaration was made, arsphenamine and emetine, indicates how despairingly limited are the actual contributions to our curative efficiency. Were it not for the wonderful strides of preventive medicine since the immortal Pasteur opened the portals of the bacteriological field to the world of research, we would have but little cause for happiness in our professional labors.

Yet, it would be quite unfair to incriminate only the unsatisfactory condition of therapeutics on this score; pathology, even as it now stands, is quite as invalid when the relations of cause to effect are scrutinized. Indeed, as Professor Barker also stated in the previously quoted estimate: "drugs of unknown physiological action cannot conscientiously be set to act upon bodily tissues in disease in which we are ignorant of the deviations from the normal." The static pathology of Virchow does not aid materially the determination of morbid processes that occur during life. As Magendie (1) wrote as far back as 1837, "the truly scientific mode of studying medicine lies almost wholly in investigating the manner in which morbid changes are produced." He rightly considered the pathological lesions as "consequences of the disease, the anatomical proofs that it has existed," but in no wise the morbid process itself.

With so dismal a picture of those features of practice which warrant our existence as practitioners and the trust the public reposes in us, you may deem the situation a hopeless one, in view of the seeming futility of the enormous aggregate of work contributed by a multitude of observers during what might be called the scientific era of medicine which began about seventy years ago. Precisely the opposite is the case. Indeed, from my viewpoint, we have in this aggregate of facts a veritable gold mine in which nuggets galore are at our disposal. It is for us practitioners to garner, analyze and synthesize what sound data this aggregate from all branches of medicine, collateral and clinical, contains; it is for us to carry on, so to say, an intellectual refining process calculated to establish both pathogenesis and therapeutics on a rational footing and eliminate em-

piricism once for all. It is the result in outline of an effort in this direction which, I may say, has been uppermost in my mind during the better part of my working life, that I will now submit to you.

Twenty-three centuries ago, Hippocrates wrote (2): "It is to the efforts of Nature that the attentive and able physician looks for guidance." Today the most virile trend of modern thought, that of immunity, which underlies the whole field of preventive medicine, is a practical expression of the principle first enunciated by the father of medicine. Why should we not likewise make it the underlying principle of pathogenesis and therapeutics? From my viewpoint, this is precisely what the endocrines enable us to do.

To make this clear, however, it is necessary to review briefly two of the ductless glands which are now known to take part in these processes: the adrenals and the thyroid.

THE ADRENALS.

Beginning with the adrenals, located as you know over the kidneys, there is apparently considerable confusion concerning the nature of their functions. In fact, there appears to be as many of these as there are physiologists who have devoted much time to the subject. For many years, the prevailing belief was that, as observed by Oliver and Schäfer in 1894, the purpose of the secretion of the adrenals was to sustain the tone of the cardiovascular system, and that as a therapeutic agent it would raise the blood pressure. But other physiologists found that far from raising the blood pressure, adrenalin, particularly in small doses, lowered it. We were also told that the adrenal secretion possessed antitoxic properties, but physiological experiments were advanced to show that it did not. Even Cannon's well known emergency theory in which fright and excitement are considered as a cause of increased activity of the adrenals has been attacked. It is obvious that physiology thus interpreted would hardly aid the clinician in elucidating any disease, general or local.

And yet all these seemingly antagonistic functions are entitled to a legitimate place, provided that they be considered as but expressions or manifestations of a *fundamental* function first submitted by myself as long ago as 1903.

Some of you may recall that at that time I attributed to the adrenals an all important function: that of endowing the hemoglobin with the power to take up oxygen in the pulmonary air cells and of converting it into oxyhemoglobin. The adrenals thus became the governing organs, as far as oxygenation was concerned, of metabolism throughout the entire body. This conception—even though it upset the philosophy of respiration which had endured almost since the time of Lavoisier and Priestley in the eighteenth century, not only met a need long emphasized by many European physiologists—that a secretion capable of clutching, so to say, the oxygen from the alveolar air, was a *sine qua non* of the respiratory function—but it also fulfilled every condition of that function. Thus, the adrenal product or adrenin was found to increase the oxygen intake and the carbon dioxide output; to increase both the depth and rate of respiration, also the heat production, temperature, etc. It has been contended that the

adrenals did not secrete enough to meet the needs of so important a function, but as shown by Stewart and Rogoff (3), the spontaneous liberation of adrenal secretion was 0.0003 to 0.001 gm. per kilo of animal—thus making 30 to 100 c.c. in the twenty-four hours—ample enough to meet the needs of the function. Other observers have confirmed the connection of the adrenal secretion with hemoglobin, also the fact that venous blood under proper osmotic conditions could be converted into arterial blood by the addition of the adrenal principle.

If we now apply this function to the different rôles attributed to the adrenals by various physiologists, its harmonizing influence becomes striking. The variations of blood pressure were simply due to the different rates of oxygenation and metabolism produced indirectly in the muscular coats of the arteries by the different doses of adrenalin. Thus *large doses* caused general vasoconstriction and a general rise of blood pressure by acting upon the entire cardiovascular muscular structure, while *small or minute doses* caused the opposite or low blood pressure by causing constriction of the smallest arteries of all, the vasa vasorum, which supply the vascular walls, and the first effect is owing to their diminutive cavity. The arterial blood entering the arteries being diminished, their muscular coats relaxed, causing passive dilatation and low pressure.

Turning to the practical side of the question, we will now find that the same fundamental functions governed in part by the adrenals: oxygenation, metabolism and blood pressure, show variations corresponding with the secretory efficiency of the adrenals, or the size of the dose of suprarenal gland or adrenalin administered. In *Addison's disease*, for instance, the salient symptoms are low arterial pressure, low temperature and myasthenia—all indicating slowed metabolism. Now we know that these are precisely the symptoms we improve or even counteract in this disease by administering suprarenal gland. But that does not mean that we can cure such cases simply by giving this substance, for it serves only to compensate for the failure of the gland due to a local morbid process: usually fibrocaseous tuberculosis. We *do* get good results, however, by treating the latter simultaneously with iodine or the iodides.

Another example of failure of the adrenals, with its attending deficient oxygenation, metabolism and blood pressure, is afforded by *Asiatic cholera*. In 1903, I urged that the symptoms of this dread disease, the hypothermia, frigidity, cyanosis, profound asthenia, rapid intermittent pulse, high rectal temperature, low vascular tension, etc., corresponded precisely with complete adrenal failure. The epidemics in Europe, particularly during the Balkan and World Wars, have proved this to be true, various clinicians having found that adrenalin in large and frequently repeated doses not only antagonized the effects of the cholera toxin, but soon removed the typical symptoms of adrenal failure. The *choleraic diarrhea* of soldiers following great fatigue was also found to be promptly arrested by injections of adrenalin, the primary cause of the disorder being exhaustion of the adrenals and virtual arrest of their secretory activity.

This same exhaustion you have all witnessed many times, doubtless, towards the close of many infectious diseases, *typhoid fever*, *pneumonia*, *influenza*, *scarlet fever*, *measles*, and other disorders. The adrenals, pushed to their utmost to sustain the *defensive fever*, which of course includes unusually active oxygenation, finally give out. As these organs sustain, we have seen, not only the vascular tension but also the contractile power of the heart muscle, heart failure threatens in addition to the other symptoms of adrenal failure. The majority of the patients who die from exhaustion would be saved if the importance of the adrenals were generally realized and adrenalin in eight minim doses were injected intramuscularly—never hypodermically—with a syringe of saline solution several times a day. I have seen cases virtually snatched from the jaws of death by this practice.

Old age is another cause of adrenal failure, the glands steadily decreasing in functional activity after middle age. *Senile pneumonia* does not correspond symptomatically with the lobar pneumonia observed in younger subjects, but presents all the signs of adrenal failure. After a brief reaction to the infection, there is practically no fever, no pain in the chest, but little cough or expectoration. Then follow a rapid fall of arterial tension, rapid pulmonary edema and exhaustion. To treat such cases in the same manner as the pneumonia of young people is to hasten death. They need stimulation from the start and particularly the intramuscular injections mentioned above of small doses of adrenalin in saline solution. The mortality from pneumonia is far from decreasing; it will never decrease until the rôle of the ductless glands in its pathogenesis is recognized.

Care should be taken, however, never to use adrenalin when, during the presence of fever and high tension, the adrenals are already overactive. Thus, injections of adrenalin are recommended by some surgeons to prevent heart failure in *anesthesia* but condemned by others owing to the many deaths it has caused. These deaths are due to the fact that the physiological action of adrenalin is disregarded. It should not be given early because the anesthetic itself, as well as the excitement and fright from which many patients suffer, stimulate the adrenals, the blood thus containing an excess of adrenal secretion. A dose of adrenalin added at this time becomes toxic; it so constricts the peripheral or terminal arterioles that the vascular tension is greatly and suddenly raised and the heart is arrested by the back pressure of the blood column. It should only be used, therefore, when heart failure threatens late in the course of the anesthesia, or in febrile disorders when the heart failure occurs as a result of adrenal exhaustion.

The same principle applies in the *disorders of the heart* itself. Adrenal gland is a remarkable aid where atony of the heart muscle exists, precisely where digitalis is indicated, that is to say, in uncomplicated dilatation, defensive compensation in valvular disorders with asthenia, hypotension, hypothermia and other disorders. An important feature in this connection is that when digitalis itself begins to fail, it is often due to exhaustion not only of the adrenals whose secretion sustain directly the heart muscle, but also to the fact that the sympathetic sys-

tem depends upon this same adrenal secretion to carry on its function. I have seen adrenalin save life in auricular fibrillation where digitalis had lost its hold. In threatening cases, adrenalin intramuscularly, with one sixth grain in a triturate under the tongue, is promptly effective. I have seen elderly people dying gradually from uncomplicated heart failure, with low blood pressure and almost imperceptible pulse and heart sounds (a natural outcome of the progressive atrophy of the adrenals which begins after middle age) virtually come to life and resume their normal occupations under the combined use of suprarenal gland and digitalis. The suprarenal substance here, supplied not only to the adrenal medulla its specific adrenal principle, but in doing so it also provided the whole cardiovascular system and the sympathetic system and its ganglia their normal *pabulum vitæ*, i. e., the substance which caused in them the resumption of normal oxygenation and metabolism.

The dozen or so of diseases briefly outlined merely serve to illustrate the important rôle the adrenals must play both in pathogenesis and treatment. It becomes a question as to the actual number of morbid processes or diseases influenced directly or indirectly by the adrenals. This question may be briefly answered by another: How many diseases are there in which oxygenation and metabolism are more or less factors of the morbid process? Close analysis of the question would show that the list includes practically all diseases which threaten life itself, the entire field of neurology and psychiatry—indeed, probably the whole domain of morbidity.

Again, the illustrative diseases described are only those in which adrenal organotherapy is indicated. How about other agents and, particularly, drugs? This is where precision is again introduced where random treatment now prevails, *for with familiar remedies we can control the functional activity of the adrenals or its effects*. Thus, the adrenals are directly stimulated by strychnine. This fact, which I first urged in 1903 and several times since (4), has recently been confirmed by Stewart and Rogoff (5) who found in the course of an elaborate pharmacological study, that therapeutic doses of strychnine, those you use every day, caused a marked and lasting increase in the production of the adrenal secretion. Now, any textbook of neurology will show by the number of diseases neurologists treat with strychnine: functional atonic disorders of all kinds, *paralyses, myasthenias, neurasthenias, shock, chronic alcoholism, cerebral anemias, depressive insanities*, and others, what the adrenals mean in these diseases. Yet, if any of these disorders happens to be one in which the adrenals are deficient, which means that the whole sympathetic system is likewise incapable, owing to deficiency of its chromaffin or medullary-adrenal substance, to carry on its functions, neurologists meet failure, since strychnine serves merely to stimulate adrenals incapable of supplying enough secretion to benefit the patient. If, however, they supply also the needs of the adrenals themselves and simultaneously those of the sympathetic system by administering suprarenal gland, or its more active and persistent counterpart, hypophysis sicca, they will obtain the desired result.

But strychnine is not the only agent which stim-

ulates the adrenals. Either directly or indirectly, nux vomica, brucine, cocaine and other cardiac and nerve tonics do likewise. So do caffeine, tea, nicotine and alcohol. Experiments and the recent war have emphasized this action of alcohol and confirmed the older observations of Hobart A. Hare that it enhanced the defensive functions of the body when administered in moderate doses and well diluted. Moreover, the value of alcohol in moderation and free dilution has been recently emphasized experimentally. It was found that it is in antagonizing fatigue wastes that alcohol is especially effective. This is again in keeping with one of the earliest discoveries concerning the functions of the adrenals, that of Abelous and Langlois, who found that the antitoxic properties of these organs were primarily the destruction of fatigue wastes. Conversely, the prolonged use of strong solutions of alcohol, such as brandy or whiskey, have been found to cause degenerative lesions in all ductless glands examined, including the adrenals, and to lower the efficiency of the defensive functions. Light beers and wines, however, were found quite harmless to these organs, owing to their inability to produce intoxication even in large doses.

I might remark in this connection that temperate laws based on knowledge, instead of the prevailing product of misguided altruism often fed, unfortunately, by ignorance and fanaticism, would soon command the respect of the American people. It is because all adrenal stimulants, by increasing oxygenation and metabolism, convey a feeling of well being, particularly during fatigue or exhaustion, that they are in such demand, especially by working men. It is not the innocent and temperate who should be prohibited but the intemperate.

Continuing the pharmacological side of the question, how can we counteract excessive functional activity of the adrenals? We have seen, for instance, that adrenalin injected early during anesthesia is dangerous and has caused several deaths because the dose is added to an excess of adrenal secretion and that constriction of all arterioles finally leads to cardiac arrest. Should we in a threatened case of this sort inject, as is now done, strychnine, caffeine, alcohol, and other drugs, which, we have seen, would further stimulate the adrenals? Obviously not. We have precise antagonists in the nitrites. As Sollmann (6) states: "The fall of blood pressure is due entirely to the extensive vasodilatation produced by the direct action of the nitrite on the arterioles." Injections of nitroglycerine, inhalations of amyl nitrite, are therefore indicated, all stimulants being avoided. Arsenic, chloral, and other hypnotics, alcohol in large doses, bromides, veratrum viride and other depressants, also include in their pharmacological action, depression of the adrenals.

THE THYROID

We will now turn to the only other endocrine considered today, the thyroid gland. Physiologists and clinicians are in accord concerning the influence of this gland upon metabolism. Kendall, to whom we owe thyroxin, by far the most perfect of the thyroid active principles yet produced, states in this connection (7): "The changes occurring in a patient with thyroid deficiency, or in an experimental animal by

the administration of thyroid, are so great that practically every cell within the animal organism is changed. The effects are felt throughout the nervous system and the circulatory system, the rate of metabolism is enormously increased, and even the skin and hair show revolutionary changes."

When referring to the influence of the adrenal secretion or organic products on metabolism, I used this term only to avoid confusion. In reality the adrenals affect but one phase of metabolism, the constructive phase as it were, that of anabolism. The thyroid gland also influences metabolism, but its catabolic, or breaking down, phase. This accounts for the familiar antifat effects when thyroid is administered. This action on reserve fats is followed by breaking down of the nitrogenous tissues themselves. When, as is well known, the thyroid is functionally inadequate, metabolism is slowed, as it is in adrenal insufficiency, but the symptoms are specific to the thyroid. In the severe forms there occurs a condition in which the oxygen intake and carbon dioxide output are so reduced that the subjects have been termed living plants. Even in such cases of cretinism, thyroid gland sometimes produces marvellous effects, veritable resurrections.

In a general practice, such cases are seldom seen. Many are encountered, however, in which the thyroid is not quite sufficiently active functionally to carry on metabolism, or rather catabolism, perfectly. These patients with *hypothyroidism* are often fat and pudgy. They belong to what might be called the torpid and morbid class—languid, constantly fatigued, somnolent on rising—all of which symptoms tend to disappear as the day wears on. They sometimes complain of headache and backache, usually between the shoulder blades, or of the sacrolumbar pains which rest in bed tends more to aggravate than to improve. Their temperature is low, and their hands are flabby, cold and sometimes damp, as are likely to be the feet, the latter being occasionally of the type termed flatfoot, and requiring central support. The skin is sallow, pale and waxy, causing the patient to appear older than his or her age, and suggesting an underlying renal trouble. Alopecia, beginning at the forehead and tending towards the occiput, is common in adults, the hair in marked cases being coarse, dry and brittle. The eyebrows tend to become shortened at the expense of the outer ends. Marked cases may also show cutaneous infiltration as in myxedema, and, perhaps, an increase of weight and even pads of fat over the clavicles. The teeth tend to become carious and loose and are particularly prone to become tartrous, with pyorrhea alveolaris as the general result.

Such patients are particularly prone to nasopharyngeal infections with aural complications through the eustachian tubes. This is due to the lowered germicidal activity of the vault where the defensive barriers are of the utmost importance owing to the constant inhalation of bacteria laden air. Why this vulnerability to infection?

A most unfortunate feature, in view of the incalculable harm it does, is the neglect in this country of the rôle of the thyroparathyroid apparatus in the immune chemistry of the body, now fully recognized particularly on the continent of Europe. It is not only a function which may be utilized to treat suc-

cessfully many obscure disorders, but one which when abnormally active, as in hyperthyroidism and dementia præcox, may cause great suffering, insanity and death.

Although Horsley, in 1892, showed that the rôle of the thyroid in catabolism included the breaking down of toxic waste products of metabolism, the theory that the thyroparathyroid mechanism took part in our defensive functions against infections and exogenous pathogenic agents was introduced by myself in 1903 and further developed in 1907. I then urged that it played the rôle of the sensitizing agent described originally by Denis and Leclef and which Wright and Douglas termed opsonin. This has been confirmed at the Pasteur Institute, the Bacteriological Institute of Liège, also in Russia and Italy. McCarrison (8), to whose labors we owe much in this connection, states in a review of the question, beginning with my labors: "The fact that the antitoxic and bactericidal resources of the body are largely dependent on the functional perfection of the thyroparathyroid mechanism is, I believe, as clearly established as is the influence of this mechanism on metabolism." His excellent book upon the thyroid gland fully confirms this conclusion.

In certain cases the development of any disorder is likely to prove rebellious to treatment and the use of small doses of thyroid gland will more or less promptly turn the tide. In *articular rheumatism* for instance we often obtain no results from the salicylates, even in large doses, but if we study such a case from the viewpoint of endocrinology, we will discern symptoms of hypothyroidism of the larval type: a tendency to cold extremities, a pasty skin with perhaps transient edemas, scant hair, obesity, eczema, psoriasis, nausea, myasthenia, etc. Now, if we give these patients say one and one half grains of thyroid daily in divided doses, we will soon find the salicylates effective. Why? Because the thyroid product sensitizes the bacteria produced by the causative focal area, tonsillar, dental, intestinal, etc., and they are at once taken up by phagocytes and broken down by the antibodies in the blood. The germs are not seized and destroyed until the thyroid hormone sensitizes them.

In *pulmonary tuberculosis*, thyroid administered to experimentally infected animals has been found not only to raise markedly the opsonic index, but also to prolong greatly their life and in some to prevent death. The blood had been found amply supplied with antibodies, complement, agglutinin, precipitin, etc., but it was only when the thyroid was administered that the animals began to improve following infection, because this hormone was necessary to render the germs vulnerable to the antibodies. The great lesson to learn from this fact is that we have been doing the right thing for years for these patients, but doing it half heartedly or too late to save them. Iodine—which alone has stood the test of time—owes its action to the fact that it is taken up by the thyroid. Another lesson is that we need no longer wait until a patient becomes tuberculous to know that he is predisposed to this disease, since all cases of larval hypothyroidism, the symptoms of which have already been described, are known to be exceedingly vulnerable, while practically all pretuberculous people show signs of hypo-

thyroidism. Preventive treatment by the iodides would do much, therefore, to reduce the mortality of pulmonary tuberculosis.

The number of diseases influenced by the thyroid gland owing to its influence on catabolism and its sensitizing action on bacteria and other harmful substances which are to be engulfed by phagocytes or other defensive agencies, and reduced to end products to be eliminated from the body, is familiar to you all. Briefly, it is the long list, including *syphilis*, *bronchial asthma*, *arteriosclerosis*, *glandular enlargements*, *osseous tuberculosis*, *psoriasis*, and other diseases, in which you have been administering iodine, especially in the form of iodide of potassium. It is in truth the thyroid hormone which does the work and when you administer iodine in any form, the gland takes up about eight and five tenths per cent. (Marine) of that administered, until the quantity it can assimilate has been reached. This event marks the beginning of the so-called physiological effects, which are not such in the least, but an effort to eliminate in every direction possible the offending and useless excess of halogen that may be present in the body at large.

We have now seen that while deficient thyroid efficiency, hypothyroidism, predisposes to infection and may even prevent the action of our remedies, increased efficiency of this gland, obtained by administering iodine or the iodides, increases defensive efficiency in many diseases. There are two other phases of the functions of this gland in disease to which a brief allusion must be made: compensatory enlargement and excessive defensive functional activity.

Compensatory enlargement is occasionally witnessed in various infections including pulmonary tuberculosis and also in toxemias, even what might be termed a physiological toxemia such as is produced by the excess of wastes during pregnancy. In both forms of intoxication, the thyroid increases in size, because it is inherently unable to undertake and carry on more than its usual antitoxic functions, the catabolism of physiological wastes. When, however, any abnormal source of intoxication occurs, a general infection, a focal accumulation of bacteria which are constantly excreting toxins, whether located in the tonsils, sinuses, teeth, gums, and other places, or in the intestinal canal as fecal stasis, or the water or food contains toxic substances, the gland tries to increase its functional activity and enlarges.

This condition, when persistent, is that familiar to you all as *goitre*. When due to an acute infection, it promptly disappears when the causative disease is spent. When, however, the source of infection or toxemia persists, as is the case when a focal infection or an external source of continuous, even though slight, poisoning occurs, it is this causative factor which must be removed. Simultaneously, however, the thyroid itself must be aided by the use of iodine or of the iodides and iodine ointments, weak enough not to irritate the skin and prevent absorption, applied over the growth. A third feature of *goitre* requires attention, however: the abnormal dilatation of the vessels in the gland—which is the mechanical cause of its excessive activity, as long ago shown by Claude Bernard. While, but *only* while, its efficiency is being compensated by the io-

ides, this abnormal vasodilatation, which causes the enlargement, can be mastered by another familiar remedy, ergotin, which causes contraction of the vessels. With these four measures carried out simultaneously: removal of the primary cause, daily applications of weak iodine ointment over the gland, and iodine or the iodides and ergotin internally, I have seen uncomplicated *goitres* disappear often with surprising rapidity.

The same process of compensative enlargement and enhanced activity may become such as to cause very serious and even fatal diseases. We have a striking example of this action in exophthalmic *goitre*, in which the tissues are, so to say, driven to self destruction through excessive sensitization and catabolism. Here, again, some focal infection or toxemia is the underlying cause, the gland becoming enlarged because it is unable normally to stand the strain and, as in ordinary *goitre*, undergoes arterial congestion to increase its efficiency. Important, however, in this connection, is the fact that in many instances the gland does not become enlarged because it is efficient and able to carry on the antitoxic strain placed upon it. Nor is exophthalmos present in all by any means. Yet, the typical tachycardia, tremor, and other signs are present—all typical of exaggerated metabolism. Here, again, removal of the source of toxemia, focal, endogenous or exogenous, absolute rest to reduce to a minimum the production of wastes which increase the defensive activity of the organ, ergotin to constrict its arteries, further aided in this disease by another powerful vasoconstrictor, quinine hydrobromide, and a diet from which dark meats, known to excite the thyroid, are eschewed, will enable you, if persisted in, to master the disease without sacrificing the gland itself or any part of it.

The last disorder to which I will briefly refer is one which has sent hundreds of thousands of children and adolescents to our insane asylums and is increasingly doing so—*dementia præcox*. That this means their practical death is suggested by the fact that in New York State alone, out of 21,070 cases in its asylums, less than one case per thousand had been discharged cured during the fiscal year ending June 20, 1917. Now there is much evidence to show that we are dealing with a disorder akin in some of the catatonic cases at least, to a condition resembling exophthalmic *goitre* in the sense that (at least from my viewpoint), the phosphorized fats which form part of the cerebral and other neurons, break down under the influence of excessive thyroid activity, induced by a toxemia, in predisposed subjects. Here again, removal of the cause, some focal infection and reduction of the thyroidal exuberance, by constricting the dilated vessels, supplemented by lecithins—organic products rich in phosphorus and a diet rich in fats, to rebuild the affected neurons, has produced recovery where the intensity of the symptoms had left no hope.

CONCLUSIONS.

In closing this elementary outline of a few of the many disorders which might be analyzed to illustrate the close relationship between the endocrines and everyday diseases, permit me to urge that I am not submitting theoretical considerations, but repeat-

edly proved facts, which you can readily verify yourselves in your daily work. I would also urge: 1, that although some thirty and odd morbid processes have been summarized in this paper, the relations between cause and effect, meaning thereby the manner in which the morbid changes were produced, found their normal explanation in every instance, and 2, that in not a single instance was a remedy advocated empirically, that is to say, without indicating how it antagonized the morbid process for which it was recommended. The endocrines alone made this possible.

On the whole, what I have submitted seems to me to sustain my firm belief that *there is a rational medicine in sight, as regards both pathogenesis and therapeutics*, provided we utilize intelligently the splendid aggregate of knowledge all the branches of medicine, auxiliary and clinical, have placed at our disposal. If we do this, and with Hippocrates "look

to the efforts of Nature for guidance" and realize that we have in the endocrines the mechanism through which Nature not only sustains the vital processes but also preserves their integrity, the days of empiricism will soon be numbered.

Endocrine Tropisms

Gonadotropism: Fourth Contribution

By D. M. KAPLAN, M. D.,
New York.

The importance of clinical endocrine studies becomes daily more apparent, and every specialty in medicine is beginning to note the benefit derived from linking endocrinology with a great number of subjective as well as objective manifestations. Even traumatism has an endocrine significance as was ably shown by Crile in his numerous and interesting contributions on this subject. It is fairly well established today that the entire human sensory motor mechanism is intimately linked with the functions of the glands with internal secretions. These secretions certainly possess a determining power in directing the functional trend of the individual, and if permitted to pursue an unchecked career will very often produce physical manifestations which will furnish interesting data for the histologists. In the majority of instances an equilibrium is maintained which need not force the individual to seek medical advice; on the other hand, many *formes frustes* as well as prodromal endocrinopathic states are not recognized until histopathological changes have become permanently established. Recognized early, such occurrences should become rarer as we advance in endocrine lore and interpretation. In this communication an interpretation of the endocrine phenomena which occur in the gonadotropic individual will be dealt with and will include chiefly the functional and subjective manifestations, interspersed here and there with histopathological confirmation of endocrine findings which are still in need of such support, but in the main the paper will deal with subjective complaints such as the physician is called upon to relieve in the majority of instances. Sundry therapeutic precepts will be offered which may not tally with the orthodox opinions, but they will be given only when the procedure adduced proved of signal and lasting benefit.

It is almost an axiom that the preservation of the race depends upon the functional activity of the gonads, and if the ego is to survive in the form of another individual it is only insured of a future existence through the activity of the reproductive organs. Hereditary characteristics and the varied nuances of character, predisposition and personality, in fact the entire makeup of the soma and psyche are embodied in and are transmitted through the medium of the spermatozoa. They carry with them dominant and recessive qualities from the male element consisting of sidechains gathered from every cell depot of the individual and also from every gland with an internal secretion. The female elements contribute their quota in a similar manner and the union of the two reciprocally complement each other in that the male recessive feature is dominated by the corresponding dominant female equivalent and vice versa.

The somatic and psychic factors which would be required to furnish the materials to make a complete male or female are not known, and the *sum-mum bonum* still remains a comparative term—for we know not where perfection exists and what is best for mankind, present or future. In so far as the physician is concerned it is his domain to prevent disease or an uncomfortable existence and to cure a given sufferer totally, rapidly and with the least inconvenience to the patient. At least that is what the sick one hopes for and what the doctor ought to strive for. To me it is not only a pleasure but a distinct duty to inform the reader of this communication of the less common somatic and psychic indices which would shed a ray of light on the interpretation of an apparently obscure case as well as to outline a therapeutic procedure based upon results obtained from its employment in more

or less analogous situations. To begin with, I make the statement that there are no men or women without heterosexual psychic or somatic appanages; I say this no matter how perfect their architecture or functions may be. Similar to the bipolarity of a magnet, every human being is likewise bisexual. In the study of gonadotropisms the quantitative determination of the heterosexual contents will have to be ascertained before any therapeutic advice is given. This is only possible with an adequate knowledge of endocrine principles and facts and the ability to collate apparently dissimilar findings. On the surface, endocrinology may appear iconoclastic, but a deeper investigation convinces one that it is a distinct step forward towards determinism in medicine and in many instances when properly used renders prognostication almost prophetic.

As you may know, there are signs which enable the doctor to determine beforehand whether a child will contract diphtheria or not. These signs have been made use of before the Schick test became a public school procedure, of course by endocrinologists only. To them dark hair implanted low on the forehead, sharp canine teeth, darkly pigmented moles, a tendency toward hirsuties or a white Sergeant's line were the indices of an adrenotropic constitution. To them also an adrenotropic child was considered far more susceptible to diphtheria than a child otherwise constituted, such as a thyrotropic, pituitotropic or gonadotropic one. This communication being concerned with gonadotropic occurrences takes cognizance of the gonadotropic importance of mumps in a child or adult, and possessing such information the doctor can predict the psychosomatic limitations in such an individual which may take place in the future. What these limitations, abnormal traits or pathological tendencies will be one cannot and ought not attempt to predict, but that they will come about can be stated with emphasis.

If it were possible to ascertain the infancy of the well known psychopaths I am fairly certain that Oscar Wilde, Zacher-Mazoch or Harry Thaw would give a history of mumps during their early life. It must be remembered that only in rare instances are the gonads affected by an inflammatory reaction as a complication of mumps; much more frequently, however, they are involved in a manner most cryptic and give evidence only later in life that their functional mechanism was peculiarly interfered with. Histologically, one rarely finds anything deviating from the average. In such instances the psychopathic soil is inherited and all it needs is the seed of environment and a flaw in the gonadal chain which takes in the functions of the adrenals and the pituitary in its manifold manifestations. But it takes a Daniel in endocrinology to interpret the Tekel Upharsin written on the exterior of the individual and which when corrected early would keep an Oscar Wilde out of a jail and perhaps a Thaw also. But one must be able to read and correct. Volumes have been written concerning endocrinology and the communication I am offering herewith is only an A B C. We shall return to mumps and consider this disease as a gonadotropic index. Whether the gonads were involved, resulting in an

orchitis or oophoritis, does not matter, nor does it follow that a severe inflammatory complication during an attack of mumps need cripple the functional expression of the gonadal apparatus.

The most insignificant attack with an ineffectual recovery is often observed in those dangerous and extrasocial psychopaths whose parents hardly remember the slight swelling which occurred during the early period of the patient's life. Evidently mumps must fall upon a soil hereditarily below par in order to produce a disturbance in the cerebro-adrenal relationship as a result of this invasion by a gonadotropic poison. Embryologically the cerebral cortex, the adrenal cortex and the endocrine cells of the gonads are interrelated. Functionally the thyroid, the pituitary and the pineal gland play a rôle in the functional activities of the gonads and in order to work correctly the gonads require the healthy support of these endocrines and only when this perfect orchestration is at hand can we speak of a *mens sano in corpore sano*.

Now then, how is one to determine the balance of power among the endocrines? What have we at our disposal to determine the tropism of this or that individual, be he a patient or not? The answer is simple: Anamnesis and status præsens. But as simple as the answer appears at first sight it is nevertheless a difficult one to follow and though as laconic as the basis of all religions, "Love thy neighbor as thyself," it is rarely adhered to. One must be generous in spending as much time as possible in order to unearth from the past the underlying cause of the trouble and to delve deeply into the diseases of infancy, advent of puberty, home life and other environmental conditions of the patient.

With this in view, I shall give a few guiding suggestions, fully cognizant of the fact that I can only offer the A B C of the topic under discussion. In view of the fact that mumps have a tendency to involve the gonads I have designated this malady as gonadotropic. Diphtheria is for potent reasons adrenotropic. Having obtained a history of mumps in your patient it is endocrinologically correct to suspect an error in the gonads functionally and at times even structurally. The patients need not divulge anything directly relative to their gonads or *vita sexualis*, and often it so happens that we must be more than discreet in approaching the subject, but the demeanor of the patient will disclose a certain degree of secretiveness as though their innermost secret is about to be placed under a microscope, thus revealing unconsciously the stumbling block which causes them to seek medical advice. We need not expect a story centred about the functional activities of the gonads. The patient will complain of a headache, more often than not supraorbital in location, again it may be on the vertex, at the occiput, or anywhere on the head, but possessing a certain periodicity in its occurrence, loss of appetite, epileptiform attacks lacking the stamp of genuineness and a host of symptoms which belong to the vast domain of psychopathology.

The next feature in the anamnesis is a most important one and deals with thoroughness with the gonadal advent, this being a particularly important period in the life of the female. Here it is the height of neglect to ascertain superficially the men-

strual functions as is often done by the busy practitioner, but an insight into the pituitary function must be obtained by a study of the periodicity, the adrenals are surveyed by a study of the pains and the thyroid shows its effect by the state of the menstrual blood. There are other questions rarely put to the patient, but which nevertheless have a telltale significance in an endocrine investigation, such as, "Where does the premenstrual blemish appear?" and strange to say some rather clever gynecologists confess that they never heard about it. "Can the napkins be easily washed?" If a leucorrhea is present it is very important to ascertain its most intimate characteristics. "Is there a distinct change in the appetite at that time and does the patient crave for sharp foods?" All these questions have a bearing upon the correct interpretation of the trouble, and furthermore possess valuable therapeutic information. Having mentioned the premenstrual blemish, I believe a few words concerning its peculiarities will not be amiss. I found it present in ninety-five per cent. of women, the rest not being certain about its appearance anywhere on the body. It appears from two to ten days before the flow is established and lasts from one to three days after. At times it disappears as soon as the menses appear. Its place of occurrence is of importance to endocrinologists as a deviation from the common location is frequently associated with frank or masked gynecological disease. In the great majority of healthy women in whom healthy gonads can be assumed to exist the blemish appears at the nasolabial furrow on the right side in the form of a small pustule at times no larger than a pin head. A gonadal error is not present if it should occur on the corresponding left side. Should it develop on the forehead, shoulders, back or chest, I would on this basis not consider the gonads as absolutely functionally intact. Appearing on the chin, it has likewise no special significance. I have by no means exhausted the manifestations appearing during this impregnation preparatory period, and I am quite certain that there will be students of endocrinology who will finish what I consider only a beginning. Dark rings under the eyes, an enlargement of the thyroid, a thickened condition of the lips and irritability will all be considered of importance in their exaggerated or attenuated appearance. Aside from the menstrual flow and its varied expression, one must not lose sight of the environment during its first appearance.

I have pointed out elsewhere it is of the greatest moment to prepare the mind of the child for this advent and make its initiation the most natural and least shocking accompaniment of womanhood. A shock in certain girls during this first gonadal crisis, for it certainly is a crisis, will bear its undesirable fruit in the future in the form of a psychic or endocrine derangement. It is therefore of prime importance to ascertain whether any shock was given to budding womanhood at that time and fully weigh the environment of the child, its health at that time, the familial status, economic reverses, curtailment of customary luxuries, studies, work, and other factors. From an endocrine point of view this may be summarized as the menstrual anamnesis.

A gonadal crisis occurs in boys also, and though

devoid of its objective innovation in the form of a flow of blood, it nevertheless has its subjective equivalents and one must be prepared to remove the secretive reserve with which the youth or young adult tries to surround his psychic *vita sexualis*. For him there are also terrors in store for which he cannot find an explanation and broods silently in a corner, or becomes absentminded, forgets his lessons, cannot concentrate, and the shock is delivered when he fails to pass his school examination and is thoroughly punished by an ignorant parent. The climax which breaks down the psyche of the boy and sows the seed for a future psychopath is not infrequently consummated in the doctor's office when the youth is bluntly confronted by the crippling results following masturbation, and henceforward the susceptible psychogonadal mechanism tries to find an excuse for its existence and an outlet for its expression. Both become unnatural and twisted and furnish the material out of which the future delinquent, the ne'er do well, and the outspoken criminal are made. For such we have many wise and unwise remedies, but, in my opinion, prevention and proper home hygiene and careful and sane preparation would relieve legislators, lawyers and judges of much unpleasant work. To go into the subject still more deeply is to purloin the domain of psychoanalysis, a much needed department of medicine in that it makes thorough history taking a part of its armamentarium.

From the examination of the patient we have still greater endocrinological support in ascertaining the tropism of the individual. Here as in the anamnestic part features are left out by the busy practitioner which are considered good information by the endocrinologists. It has not become common property that the teeth have been given an endocrine importance by myself in an exposition of the subject under the title of *An Endocrine Interpretation of the Dental Apparatus*, which appeared in *Endocrinology* for April, 1917. This has been emphasized before. Since then a few careful observers have supported my contention and I shall here give a short résumé of the teeth in gonadotropic individuals.

In the gonadotropic individual the dental apparatus carries a very striking earmark of the tropism. It is well known that the middle upper incisors carry a message from the pituitary and that the canine teeth designate the individual's adrenal equipment. The upper lateral incisors do the identical function so far as the gonads are concerned and furnish an earmark, though an unexplainable one, of the somatic and functional completeness of the gonads. Why this is so I do not know, but on many occasions the poor implantation of the left upper lateral incisor, together with a careful reexamination of the patient physically and anamnestically proved that the patient had an ovarian disturbance instead of the suspected appendicular trouble. If, *ab ovo*, the gonads are the individual's points of least resistance in so far as trauma is concerned, they will show on the surface and in the patient's upper lateral incisors the stamp of teratological or functional defect. As may be gathered from the tooth involved in a right ovarian situation the relationship is a crossed one in that the left

upper lateral incisor is involved. The aberration from normal consists in a poor implantation, its mesial edge showing forward and at times even overlapping the middle incisor. One must be careful in differentiating the real torsion from the apparently twisted tooth having no gonadal significance and resulting from a too small upper jaw, the condition being one of crowding, and hence without a gonadal endocrine expression. A similar twisted state in the right upper lateral incisor points to the left gonad.

A few years ago I had occasion to visit my Alma Mater hospital and related my endocrine experiences; the house physician at that time suggested that I be given an opportunity to prove my findings. They had a number of patients brought into the room, among whom was one who had a congenitally absent testicle, the other being normal. I proceeded to examine the teeth of the eight men and by elimination one was left in the room as the most likely one. You can imagine the surprise of the doctors when I picked the right one among the eight. An almost similar occurrence took place when I accompanied a doctor on his rounds in one of the big hospitals in this city. A woman who had a diseased ovary removed was shown to me and I was asked by the doctor to determine, in an endocrine way, which one was absent. The correct answer puzzled the doctor until I imparted to him the method of analysis. Now, I determined the side on which the ovary was removed, not by changes that took place since its removal, but from an analysis of the teeth, which imparted to me the information that one ovary must have been deficient and hence the likely one to be affected by a disease process requiring surgical interference. In case of the absent testicle I also determined from an analysis of the dental apparatus which one was delinquent. In the case of a near relative I took the stand against the opinion of one of the most noted surgeons in the land in that I considered the condition not one of surgical appendicitis but rather that of an ovarian neuralgia. The same individual had more than six attacks, the last one appearing nine years ago. She is perfectly well today, and I am certain that there are many others who had the same trouble but were operated upon for lack of information of the kind used to save my relative from the knife. The relationship as mentioned before is a crossed one, the left upper lateral incisor indicating a functional or structural abnormality in the right gonad, the right one pointing vice versa.

Such individuals, when they give a history of mumps, furnish enough data to the discerning physician to keep him on the lookout for gonadal situations, psychic or somatic. Now comes another instance forever fixing the significance of the gonadal teeth in my mind. A woman of forty-five came to the hospital for pains in the abdomen and left side. She had never menstruated, was married many years, was never pregnant. When I examined her mouth the striking feature was the entire absence of both upper lateral incisors. Upon questioning her about them I was told that they never erupted. I made a tentative prognosis of congenital absence or primitive development of her gonads. By a careful gynecological examination the adnexa

were not palpable and a rudimentary uterus was found. Since then the utility of this sign has been established, at least in so far as I am concerned.

The reader will gather from what has been said that any individual possessing marked heterosexual stigmata carries this excess at the expense of his own psychosomatic gonadal storehouse. Hence it is to be taken as significant of diminished masculinity if a man has to shave only once a week, has a squeaky voice, shows a gynecomastia, pubic hair with the apex downward, venus dimples over the sacrum, lack of hair on the shins, and an eye suggestive of exophthalmos. If the case is that of a woman who presents a hairy upper lip, or undeveloped breasts, or hairy shins, or a masculine distribution of the pubic hair (apex upward) she likewise does so at the expense of her psychosomatic femininity. The man and the woman of these types suffer. If they do not complain of any discomfort at the time, they nevertheless possess certain characteristics in their demeanor sufficient to draw the attention of the critical observer. Their gonadal equipment is incomplete and often their complaints which have been classified as sexual neurasthenia, for the sake of convenience, have received only superficial attention and if anything only makeshift therapy.

In the records of my friend and teacher, the late Dr. Joseph Fraenkel, will be found the case of a man who proved to be a nuisance to himself and others and a particular pest to the doctors whom he consulted, who was completely cured, much to the surprise of the man himself and his previous physicians, by a vigorous therapy with ovarian extract. He received other endocrines before but only the latter had an effect upon him. Cases can be multiplied but would introduce repetitions, and there are by no means instances lacking where women showed their only improvement after a suitable therapy with sperminum Poehl by mouth or injection.

For me to go into the hopeless domain of incurable teratological defects, such as is shown by the gonadal expression in cases of adiposogenital dystrophy or cases of gigantism would be a waste of time. Whether it is best to operate upon their pituitary in the absence of serious intracranial symptoms or not I leave to the surgeons. To my mind surgery will not untie the Gordian knot of their endocrine tangle. However, it is in our power to alleviate their subjective discomfort by proper endocrine therapy, bearing in mind their gonadotropism. For the endocrine therapist, however, there is a vast field for doing wonderful work with those chronic headaches, pseudoepilepsies, sexual abnormalities and other conditions which show the tropisms described as gonadal in these pages. You will find the headache associated with the menstrual phenomena, that they have a certain periodicity, that they are supraorbital and occur in those who show one or more of the gonadotropic signs spoken of before. In the pseudoepileptic there will be an absence of tongue biting, no injuries, the patient will not display the abject hopelessness in his facial expression which invariably stigmatizes the incurable epileptic, and there will be some sort of a hitch in his psychic or somatic *vita sexualis*.

Only half of the good will have been accom-

plished if we do not warn the patient against a too hasty oophorectomy, forgetting that much good can be obtained from a judicious endocrine therapy and also that every pain in the appendical region need not require the knife and that this pain may come entirely from a faulty ovarian function. Here an endocrine interpretation will be of great benefit and save the patient from an unnecessary operation.

Now as to the use of the various endocrine products: Let me warn the beginner against all advertised products. Let me warn him particularly against the readymade diagnosis and the readymade shotgun pill. He who indulges in such therapeutics will learn nothing about endocrinology and will frequently do more harm than good. There are a great many manufacturing concerns who dry, rub and extract part of various quadrupeds and sell them to the unsuspecting medical public as endocrine products. Deal with long established reliable firms. Shun the business seeking firms who deluge your office weekly with literature which is less than useless in practical instances.

Now as to the drugs themselves. Let me inform the doctor that there are few instances where the firm gives due consideration to the endocrine status of the animal used for the furnishing of the particular gland desired. For instance, one will not deny the fact, unless he is totally ignorant of endocrine interrelationship, that an animal whose gonads are diseased cannot furnish a good gonadal extract, testicular or ovarian. Not only are the gonadal extracts useless from such an animal but the pituitary gland of such a beast also suffers and at the expense of its endocrine constitution. Such a pituitary extract may have certain biological standards equal to the healthy and unchanged gland, but endocrinally it certainly cannot be as potent as the healthy animal's pituitary.

The crux in the manufacture of pituitary extract is had when we have to admit that our extracts are made chiefly from structures obtained from castrated bulls or steers. Such pituitary extracts, at best, do not come up to the requirements of discerning endocrinologists. Let us hope that this defect will be removed when endocrine therapy will play a rôle equivalent to its possibilities. Another drawback is the method of killing steers for the obtaining of suprarenal glands. Not only is the gland functionally altered as a result of its unbridled existence devoid of its gonadal check, but the steer is brought into contact with all the horrors so graphically portrayed by Crile when it views a row of slaughtered animals hanging with heads down and throats cut and gushing blood. His adrenal apparatus is profoundly affected, resulting in a desire to escape or to fight. Not infrequently such a scared animal runs loose in an abattoir making things lively for the slaughterhouse attendants. During this brief period the adrenals of the steer receive numerous demands for more adrenalin which must be sent into the blood stream in order to supply the muscles with defensive powers. The demand is continually increased even while the animal is being hoisted up and even while his throat is being cut and even for a few minutes after that. From this steer the adrenals are removed in a much depleted

state and from such glands the manufacturers make their extracts. This is the story of the adrenals obtained from animals killed by the kosher method. The preliminary stunning of the steers such as is used in the west is much more desirable in that it eliminates to a marked degree agony adrenalin. Of course the blood pressure raising principle is present in all adrenals, but there are factors other than pure blood pressure raising which are of importance to endocrinologists, and it stands to reason that during the brief period of time that the animal is subjected to such selfevident shocks that his adrenal equipment must suffer and that an extract made from such material is by no means the greatest desideratum.

Another endocrine product is ovarian extract and corpus luteum. The latter is and properly should be obtained from healthy pregnant cows. I have my suspicions about healthy cows being slaughtered, but until we obtain proper standardization of endocrine products by the government we will have to be satisfied with makeshifts. Mammary extracts are made from glands obtained from nonpregnant animals. There are very many purely technical considerations to be disposed of, but they are of no direct interest to the therapist.

Nor is the subject of endocrines exhausted without a word of advice as to administration. The chronic habit, and it is nothing but a habit, to prescribe drugs, with the exception of castor oil, to be taken three times a day, is a farce and entirely devoid of true therapeutic principles. If one dose accomplishes the desired effect there is no necessity to repeat it; if it is necessary to repeat it I do not see the advantage of giving it only three times a day. Why not every hour if we are anxious to obtain a therapeutic expression of its capabilities in a particular train of symptoms?

With endocrine products one has to deal carefully, and this is the reason why I am so much against the readymade diagnosis and the accompanying suggestion of the manufacturer who takes upon his shoulders the onus of the expert and tells the doctor to give this in *petit mal* or that in ovarian neuralgia, or in a dozen other conditions. If one cannot work out his own therapeutic salvation the manufacturer of drugs with hit or miss tactics will never help you.

In prescribing thyroid extract begin with small doses only, less than a quarter grain, for many unforeseen unpleasantnesses may arise when a beginner uses this drug. There are instances when one may give as much as thirty grains a day, but before doing this one must be absolutely certain that it will do no good in smaller doses. Suprarenal extract by mouth may be given from one sixth up to one grain at a dose, repeated as often as is necessary, even up to a dose every half hour. Ovarian extract must be used in larger doses, say one grain every one or two hours as the case may be. Of mammary extract I have given as much as 120 grains a day for a week and obtained my result in removing the depression in a girl of fifteen, whom I consider a beginning dementia præcox. I do not state that a cure occurred in this instance, but only wish to bring out the size of the dose and its effect,

at least in this instance. As yet we have found no cure for this disease, even with the endocrine drugs.

Pituitary extract gave me a great deal of satisfaction in a few cases of epileptiform attacks and I used it rather sparingly, giving one quarter grain every other day and watching the outcome. It removed in a few instances the tongue biting, in others the duration and severity, and in all the great prostration and temporary lethargy that follows the convulsions. For certain headaches pituitary extract is of invaluable utility, but it must be given with caution. In gonadotropic states, physiological or pathological (gonadoadvent or gonadopause) this extract is frequently the only drug which will remove the great host of inconveniences from which the patient comes for relief. In the psychogonadal

syndromes one will have to use seriatim, pituitary, gonadal extracts or suprarenal gland extract. The latter will occasionally do wonders, and in a short time. A combination of adrenal and gonadal extract was of transient and temporary use in a few cases of dementia præcox, but its effects upon this disease cannot by any means be considered as even approaching a cure. Lack of space prevents me from going deeply into the finer therapeutic technicalities, and I shall consider this communication as having done its bit of good if the doctor will use his own diagnosis and try for himself, beginning with small doses at infrequent intervals the many single endocrine drugs (not using combinations at all), and establish the utility of animal gland extracts for himself.

8 WEST EIGHTY-SIXTH STREET.

A Study of High Blood Pressure in Women from the Endocrine Point of View*

By JACOB GUTMAN, M. D., F. A. C. P.,
Brooklyn, N. Y.

This communication is a protest against the use of the designation essential hypertension as applied to cases where high blood pressure exists without the presence of any discoverable pathological lesion. The term essential, employed in this connection, has never been clearly defined, and, like much other medical phraseology, merely serves as a cloak to lack of precise knowledge. In place of this vague term, I should like to offer another which seems to be more exact, and founded upon a sound physiological basis.

The condition of high blood pressure is far too grave a one to be dealt with lightly. The reckless use of the term essential is inexcusable. In the series observed by me, no case was permitted to be designated as essential until the most rigid investigation had ruled out every possible cause for the condition. In each instance the Wassermann test and its modification were made; careful analysis of the blood did away with the possibility of nitrogen retention or the beginning of nephritis; a diligent search was pursued for any evidence of arterial, cardiorenal or luetic affection. The chest was röntgenographed in a search for aortic disease, and the condition of the teeth, the tonsils, the appendix, the gallbladder, the uterus, adnexa, rectum and every other organ which might by any possibility harbor infection, or under any circumstances give rise to arterial hypertension, was minutely scrutinized. Only when all these efforts had failed to produce any causative factor to account for the high blood pressure was it deemed proper to call a case essential.

Failing to find a reasonable pathological basis for the condition in certain cases led the author to seek for an endocrinological explanation. A careful study

of the features and constitutional markings of the women who registered a high blood pressure without pathological evidence to which the condition might be ascribed, soon revealed them to be of the pituitotropic type. From long continued clinical observations, the author, in common with other endocrinologists, has learned to classify different individuals in accordance with their exhibited characteristics, basing the different classifications upon the external somatic markings and functional expressions.

ENDOCRINE TYPES.

The principles upon which the classification into types is founded have already been described (1), together with the influence of the endocrines upon constitutional development. The influence which the inherited forces of these glands of internal secretion are able to exert is intense, even in the earliest period of life. By means of it the individual is molded into that form which is characteristic of his ancestors, nationality and race; it determines all the features of his body, all those traits of character and idiosyncrasies which have something in common with those of his progenitors. A certain endocrine may take a leading part in this construction of the individual, exercising an all comprehensive influence, which results in the creation of an individual peculiar to that endocrine type, so that such an individual may represent a pure type and can be named after the particular endocrine responsible for his physical structure. Thus, a pituitotrope is one whose development was governed by the hypophysis; with the thyrotrope the thyroid was the chief molding influence. The type produced by the influence of one gland is strikingly different from that produced by some other gland,

*From the Medical Clinic, Brooklyn Diagnostic Institute.

so that beings having a common glandular origin can be readily segregated into a particular class. To the endocrinologist these different types are so distinct that he is able to differentiate them as readily as he would differentiate the breed of an animal or species of a plant.

Not so readily classified, however, are those people whose development has been influenced by the joint action of two or more glands, usually designated as mixed types. Where several glands have had a share in the molding of an individual, their action may have been coincident, or have occurred at different chronological periods. In these mixed type individuals some features will have one glandular origin, and some another, so that at times it requires a great deal of skill to decipher these different indications, and establish the correct constitutional classification of that individual. Being much more complicated in their features, their functional expressions and predispositions, they are by no means as readily classified as those of the pure or single endocrine type.

Bearing in mind that human characteristics are the result of endocrine activities, and that each gland has its allotted share in human development, also that any one of these glands is able to have a predominating influence, wider than that of any other gland, it is easy to understand that the status and functioning of the organs of any particular individual depend upon the state of the controlling glands. If, through disease or otherwise, an endocrine system becomes deranged, the organs under its control, whether in the first stages of development or later in life, will exhibit somatic or functional evidences of the altered condition of the particular endocrine involved. Disturbances in an endocrine are accompanied by definite organic alterations, pathological, functional or psychical. The progressive pathological involvement of a gland may lead to the most astonishing changes, transforming an individual to an extent which may make him unrecognizable. He may alter in stature, in bodily contour or complexion, the shape of the hands and feet may change, the proportions of these extremities, the quantity and distribution of the hair, and, in addition, there is frequently a change in the mentality, habits, character, attitude, disposition, and other psychic qualifications of the individual.

There is a definite relationship between glandular affections and the nature of the symptoms produced in the organs controlled. Definite disturbances in the glands of internal secretion result in definite changes in certain organs, no others being affected. The thyroid, for example, however, altered functionally or anatomically, acting upon certain particular organs, produces phenomena which constitute a syndrome characteristic of its peculiar disturbances. The hypophysis, if affected in a similar manner, displays its condition through other channels. It selects another chain of organs and creates a syndrome different from that brought about by the diseased thyroid. No other gland, when affected in the same manner, can produce a symptomatology resembling that of either the thyroid or the pituitary.

If we compare the symptomatology of two known disturbances of the endocrines, their striking

difference and peculiarities become apparent. Analyzing the symptoms of Basedow's disease, which is the result of a disturbance of the thyroid, and comparing them with those of acromegaly, a hyperfunction of the pituitary, we will soon be convinced that the organs involved in the first case are of an entirely different type from the other, and also that the nature of the involvement is wholly dissimilar. In Basedow's disease, the cardiac, vascular, nervous and cutaneous systems exhibit thyroïdal disturbance; in acromegaly, the osseous, autonomous, sexual, acral and gastrointestinal systems carry the pituitary burden. The organs involved in the two conditions have nothing in common, nor is there any resemblance in the symptomatology induced or originating in them. Without mentioning the symptoms of these two conditions, which are generally familiar, it is certain that anyone having knowledge of them cannot fail to assent to this statement. The variance in the two symptomatology is due to the different systems and organs controlled by individual endocrines, each one displaying its condition through the organs it controls in a manner peculiar to itself, either directly by its excretions or hormones, or indirectly through the influence of these hormones upon the nervous system. Hence the symptomatology will differ according to the gland which is involved and the nature of that involvement.

PITUITOTROPIC CHARACTERISTICS.

In view of the pituitary tropism of the women manifesting arterial hypertension, it seems necessary to touch upon at least some of the most prominent characteristics of this type. The pituitary is endowed with numerous highly specialized and powerful forces. Some of these are in control of somatic features, others of functional. The somatic controls determine the volume and form of most of the bodily organs (the nose, glabella, malar prominences, superciliary ridges, maxillæ, lips, tongue, extremities, and viscera). Thus, such anatomical peculiarities as the height and general bulk of the body, the size and shape of all acral parts, the form and position of the teeth, the structure of the nasooropharynx, are controlled by the pituitary. Pituitotropic individuals invariably present some peculiarity of any or all the organs mentioned above; one individual may exhibit only a few markings, such as a fleshy nose, a receding lower jaw, or spaced teeth, while another may present hypertrophied tonsils, lengthened extremities and voluminous sinuses. Both, however, upon close investigation, will be found to possess a sufficient number of structural and functional features to identify them as of pituitary makeup. No similar peculiarities are even encountered in persons of other endocrinological type.

The following are the most prominent functional controls of the pituitary: the periodicity mechanism which assigns the time when the teeth are to erupt, puberty to begin, and menstrual cycles to occur, which marks the period of pregnancy, the onset of labor, and the occurrence of menopause; or limits of time of sleep and its awakening. Also such phenomena as the ocular (strabismus, enophthalmos, exophthalmos, hemianopsia), the cardiac (bradycardia, arrhythmia), urinary (pollakiuria, polyuria, dysuria, glycosuria, enuresis nocturna), gastro-

intestinal (spasticity, atonicity, ptosis, dyschlorydria), and other important functions are under pituitary domination.

TROPISM OF ESSENTIAL HYPERTENSION.

During the past few years I have been able to conclude, from the observations made in the study of women of the essential hypertension type, that they were all in reality pituitotropic individuals. They exhibit many of the features enumerated above. Their physiognomy, in most instances, is so typically pituitotropic that it necessitated but little effort to determine their type. On the other hand, in another numerically greater series of cases where the high blood pressure of the patients was found to be associated with definite pathological lesions (renal disease, cardiac affection, arteriosclerosis, infection, uric acidosis, etc.), the features and endocrine markings were not pituitary but those identified with other glandular types. In those cases (cholecystitis, pelvic disease) there was a preponderance of thyroidal markings; in others who suffered cardiorenal complications, the adrenal markings appeared to be predominating.

Riesman (2) in a recent article called attention to a class of hypertension cases observed by him in females. He noted the following characteristics: First, the women were of short stature and greatly exceeded their average normal weights; second, they had passed through multiple pregnancies; third, they were free from high tension causing diseases; fourth, they were at the menopausal age or over; fifth, they were inclined to constipation and similar gastrointestinal disturbances; sixth, they presented evidences of left sided cardiac enlargement without arterial, renal or retinal pathological changes.

A study of Riesman's cases, even from the meagre description offered, leads to the conclusion that they also were pituitotropic. The description he gives—obesity, shortness of stature, multiparity, constipation, and menopausal age—suggest pituitary involvement. He does not associate these with the constitutional habitus of the patients, but merely mentions them as observed characteristics, and offers in explanation of the hypertension incidents in the life of the patient, such as worries associated with household cares, special trials and tribulations of the soul, brought about by multiple gestations, deliveries, and the caring for many children; also physical and mental strain incidental to the menopausal period and other similar events. While I am in full accord with his observations with reference to the type, I do not accept the explanations offered. The causes he mentions are insufficient to produce permanent high blood pressure. Emotions and other mental oscillations, as may be incited through multiple pregnancies, raising of children, and other factors, according to Crile, exercise a powerful influence upon blood pressure, but this is principally effected through the adrenals, and is, moreover, transitory. The change of blood pressure disappears with the termination of the provocative act and leaves no permanent effects. Emotions are more pronounced in males. It is a rare occasion when a woman suffers a ruptured bloodvessel from an acute intravascular hypertension, following violent emotion. Only in individuals of the adrenal

type, the sanguineous, erotic or apoplectic, is it common. Females of the so-called pituitary type are, as a rule, unemotional; on the contrary, they are rather tranquil and respond slowly to emotions. Hence emotions cannot be considered as fundamental in the production of permanent high blood pressure. Even Riesman does not appear to be fully satisfied with the explanations offered, and hastens to add the probability of an endocrine basis going to the extent of recalling the common association of arterial hypertension with exophthalmic goitre and acromegaly.

An analysis of the characteristics enumerated by Riesman and observed also in all of my series offers material for discussion and conclusions. Shortness of stature and obesity are hypopituitary incidents. Pituitotropic individuals of the Fröhlich type show a disposition toward shortness and bulk; those of acromegalic tendency lean toward height and slimness. In my cases all of the patients were of the short variety, while the fat distribution was of the same character as observed in dystrophia adiposogenitalis, i. e., the buttocks, hips, upper thighs, mons veneris and breasts were the storage places of fat, and not the other places which harbor the adipose tissue in myxedematous, Brissaud, Loraine, or exogenous types.

Multiple pregnancy is another interesting factor, and must also be looked upon as a pituitary feature. How hypertension is brought about by multiple pregnancies may be thus explained: The hypophysis, it must be recalled, is vitally concerned with the physiology of gestation. At the very onset it begins to hypertrophy in order to meet the extra demands to be made upon it throughout the entire period of pregnancy. It is concerned with the rhythmic uterine contractions, the period of gestation, the onset of labor, the expulsion of the fetus, the uterine involution, and many other events during this trying period of the woman's life. The hypertrophy involves mainly the anterior lobe, but does not leave the posterior and middle entirely untouched. The enlargement progresses to the hour of delivery, and is particularly marked in pituitotropic women. Indeed, they often change into miniature acromegalics with noses increased in size, lips fleshy, eyes protruding, teeth spaced and prognathic, cheek bones enlarged, voice husky, etc. After delivery the pituitary begins to lessen in volume, but the decrease never equals the former increase. After each successive pregnancy, the hypophysis remains larger and larger, so that after a number of child-births it is several times as voluminous as during the nonchildbearing period. The sella turcica in a multiparous skull may be easily distinguished by the relative depth of the fossa, the straight position of the dorsum sellæ, the small posterior clinoids, and the broad infundibular space. The hypertrophy of the pituitary during pregnancy is necessary, as it must provide for the greater hormone production demanded by the new circumstances and in preparation for the most trying event, labor, which demands an enormous amount of vital and expulsive force. But at no time can force be properly elaborated unless supported by a corresponding blood pressure, raised to the standard required in con-

formity with the demands. The rise is caused by an added supply of blood pressure raising hormone, poured into the blood stream by either the pituitary or the adrenals. In the event of pregnancy and labor it is the former which is the chief source; hence the hypertrophy. After labor the demand is discontinued, and the overproduction of hormones is stopped, but neither the hypertrophy nor the hormone production returns to the former level; both remain higher than before the terminated pregnancy. Thus with successive pregnancies the remainder accumulates, so that at menopause it amounts to a considerable figure, adding greatly to the height of the multiparous woman's blood pressure. This is the reason why many pregnancies play an important rôle in the etiology of essential hypertension in pituitotropic women.

The menopausal period constitutes another interesting feature of essential hypertension in women. The time of menopause is determined not by the ovaries alone, but also the hypophysis. An early or late menopause is established through the pituitary and not through the ovaries as commonly believed. Menstruation is not a local event, but a general one with local manifestations. If an artificial menopause is forced upon a woman in whom a double oophorectomy has been performed, all general symptoms common in her previous menstrual periods will manifest themselves every month without the presence of local molimina, because the periodicity phase of her pituitary remains intact and functioning. The same occurs also in puberty, another periodicity function of the pituitary. If this gland ripens at an earlier period than the ovaries, which either because of immaturity or disease are as yet unable to assume the task imposed upon them by puberty, the girl will menstruate vicariously in the form of epistaxis or rectal hemorrhages, or there will be other manifestations of pituitary congestion such as migraine headaches, visual disturbances, malaise and psychoses. The pituitary and ovaries, though both concerned with menstruation and menopause are nevertheless independent organs and may functionate independently for some time. In all known pituitary diseases a change in all rhythmical phenomena associated with feminine function is a common observation, irrespective of the concomitant normal state of the ovaries.

At menopause the pituitary is relieved of one of its functions, menstrual periodicity. During the menstrual life of a woman the uterus, whether pregnant or not, contracts rhythmically at specified periods. This is accomplished through the hormones of this endocrine gland, which after menopause are utilized in another direction, that of the arterial musculature. The added smooth muscle contracting hormone, in this new field of activity, is instrumental in raising intravascular pressure and tension. The author is still further encouraged in his belief by the facts obtained in several other cases, those of sterility. In these the blood pressure was high without causes to account for it; there was a pituitotropic constitution and sterility. Perhaps their pituitary hormones meant to influence the uterus were at all times active in their arteriomusculature, and, therefore, the cause of their high pressure.

PITUITARY HYPERTENSION AND ITS MECHANISM.

Granting that essential hypertension occurs in women only of the pituitotropic constitution, then what is the mechanism through which the tension is maintained at high level? This may be answered by the statement that the high tension is induced through increased production of a blood pressure raising pituitary principle, a hormone continuous in its action in behalf of an organism demanding an increased supply, and by an organ specially adapted to meet the demand.

In general, intravascular pressure is physiologically maintained by two factors: the rhythmic contractions of the heart and the peripheral arterial resistance; the other factors, the total volume of the blood, its viscosity and the elasticity of the vessel wall are of less significance. Each cardiac contraction forces an extra quantity of blood into the vascular system, adding to the volume in the already filled tubes and increasing their pressure. The peripheral resistance is sustained by the tonic contraction of arterial musculature which is stimulated for this purpose by the direct effect of the ever active endocrine hormones through the agency of the nervous supply. The two hormones known to sustain cardiac contractions and tonus are the adrenal and hypophyseal. The relationship of the former to the circulation is well known, but that of the latter is less understood. Food media introduced into the system serve only for the nutrition and rehabilitation of worn out muscle fibres, and play no part as direct stimulants of blood tension. Extractives also imbibed in food are not physiological agents and bear no relationship to permanent high blood pressure unless added continuously to the blood stream. Hence these substances cannot be looked upon as agents instrumental in the maintenance of vascular pressure.

The administration of the only isolated pituitary extract is known to be followed by an increase in blood pressure. This rise, as shown by physiology, is due to several factors: 1, the stimulating effect upon the cardiac muscle, on the contraction of the coronary vessels; 2, the stimulation of the vagus with slowing of the pulse and more forceful cardiac systoles; 3, the contraction of the peripheral vessels, especially the mesenteric; 4, the contraction of the peripheral renal vessels in contradistinction to their dilatation by adrenal secretion. All these tend to maintain intravascular tension and to increase it, if the physiological effect of the hormone is augmented. It is selfevident that an increased flow of hypophyseal secretion in the circulation, however induced, must result in an increased blood pressure, and that an endogenous hormone, originated in a living, functioning pituitary, must be more powerfully active than the exogenous, artificially prepared from animal tissue and introduced from without.

CONCLUSIONS.

No case should be designated as one of essential hypertension until every possible pathological factor has been excluded. For this reason, hidden infections of the tonsils, teeth, sinuses, appendix, gall-bladder, colon, uterus, adnexa and rectum must be sought for persistently and disclosed if present. Also such other causes as syphilis, aneurysm,

sclerosis, saturnism and similar general states causative of high tension must be excluded.

Essential hypertension in multiparous middle-aged pituitotropic women is due to an increase of blood pressure raising pituitary hormone produced by a greatly hypertrophied, hyperfunctionating hypophysis.

The pituitary hormone is a normal factor in the maintenance of arterial hypertension through its effect upon the cardiac and arterial musculature, the renal and peripheral vessels.

The term essential, in this type of cases, is inappropriate and inadequate, and should be superseded by the term hypertensiodyspituitaria, which is more rational and scientific and based upon physiological data.

Hypertensiodyspituitaria constitutes no contra-indication to surgical interference whenever this is required.

The Endocrines as Factors in the Causation and Treatment of Dysmenorrhea*

By WILLIAM V. P. GARRETSON, M. D.,
New York.

Having eliminated by careful gynecological examination, the usual static causes of dysmenorrhea, recourse to the routine procedures, e. g., curettage, dilatation of the cervix, antispasmodics, upbuilding tonics and other methods has long been customary. The histories of patients subjected to such treatment with no resulting benefit are legion. Many women at each menstrual period suffer as much discomfort as the average primipara during labor.

To appreciate the endocrine etiology of dysmenorrhea one must revert to a consideration of the vegetative nervous system and recall that the integrity of its functional balance is dependent upon proper hormonal balance and that there is a definite interrelationship between both as well as between all glands of internal secretion. The vegetative nervous system may schematically be likened to a finely poised balance beam resting on a pivotal support suspended from thyroid to ovary in the female or testicle in the male, the plane of the pivotal point being heightened or lowered as hyperfunction or hypofunction of these reciprocal glands may occur.

The left half of this visualized balance is the sympathetic portion of the vegetative nervous system, and the right half the autonomic or extended vagus; this schematic right and left subdivision peculiarly exists in the clinical expression of vegetative dominance in the production of right and left sided symptomatology. This is an observation of remarkable clinical interest, proved beyond all possibility of being mere chance or coincidence. By endocrine interpretation as reflected in the structural makeup of individuals, right and left sided symptomatology and pathology may be determined. It is definitely known that the sympathetic portion of the vegetative nervous system is activated and maintained in balance by adrenalin, the hormone of the suprarenals, while the autonomic portion, although not accepted generally, I believe from clinical observation is dominated by the posterior or nervous portion of the pituitary inclusive of the infundibulum. (Vagotonic effect of pituitrin on intestine and uterus.)

The vegetative nervous system has its segmental distribution in the spinal cord. Anatomical, histological, pathological and physiological proof of this now exists. All states of hypoadrenia, regardless of the etiology, lower the sympathetic tone and create a condition of vagotonia, which may be segmentally expressed as a local vagotonia or evident as a general vagotonia when all segments are affected. Hyperadrenia produces a sympathicotonia. Hypopituitarism produces a lowered vagal tone with resulting sympathicotonia, while hyperpituitarism creates a vagotonia.

At the developmental epoch in both sexes with the onset of gonadal function, stimulation through thyroid, suprarenal and pituitary by the introduction of the sex gland hormone initiates an imbalance in the vegetative nervous system and the various psychical and physical symptoms incident to this period are segmentally or generally expressed until a stabilized adjustment is effected. At this period in the young girl with inherently sluggish or deficient gonads, compensatory stress is thrown upon thyroid, suprarenal and pituitary glands. Hyperthyroidism is frequently produced to a mild degree and the enlarged thyroid at this period of life is not uncommon; likewise in hypogonadism, thyroid swelling is always present with each menstrual period. The sequel of gonadal exhaustion following too frequent pregnancies, creates a similar compensatory effort. The selective compensatory stress reaction will be expressed first through the gland which dominates the individual's physiology and this is always objectively evident in the structural type of that person. In thyroidal types, thyroid compensatory effort is dominant. In suprarenal types and pituitary types such compensation effort is primarily evident through those glands respectively. In mixed types the predominant gland is the one which responds first. In these compensatory stress reactions the gland which first responds bears the brunt of the load and is the first to be exhausted with sequential hyperactivity occurring in the associated structural determinant. Prolonged stress leads to exhaustion and thus the entire chain may slump.

*Read before the West Side Clinical Society of New York, May 12, 1921.

In the topic under discussion, namely, dysmenorrhoea, there is most generally a gonadal dysfunction and essentially always a state of vagotonia, segmentally expressed through the sacral autonomic. This vagotonic state is always due to a resulting ultimate compensatory exhaustion of thyroid, or suprarenal, or both, or a compensatory overaction of the pituitary. To determine which is the case is a relatively easy matter. Hyperthyroidal symptoms in varying degrees are now familiar to most of us. Hypoadrenia is likewise easily differentiated from hyperpituitarism.

Upon these deductions depends the therapeutic indications. The pituitary is well known as a most potent synergist to the ovary and with every menstrual period there is associated pituitary activity frequently occurring in compensation to gonadal fatigue and causing transient swelling of the pituitary to the degree of creating intracranial pressure symptoms, e. g., pituitary headache, visual disturbance from pressure on optic nerves, nausea and vomiting and either general or pelvic vagotonic symptoms, the latter being characterized dysmenorrhoea. I have seen acromegalia produced by this compensatory hyperfunction of the pituitary gland when its anterior lobe has been activated by continued effort on the part of the pituitary to aid exhausted ovaries or to compensate for their total loss by surgery.

GONADAL DYSFUNCTION.

Gonadal dysfunction or genital structural abnormality is associated with definite physical markings. Torsion of teeth, absent lateral incisors or canines are always indices of such conditions. Atrophic areas or white spots on the finger nails are always associated with gonadal dysfunctions. Abnormally large hips and lower extremities, disproportionately greater in circumference than the arms and thorax present a structural type created by ovarian dysfunction. As stated in previous papers, from simple observation one may be greatly enlightened as to

the underlying physiological disturbances which are productive of definite symptoms.

The vagotonic state produces contraction or spasm of uterine muscle, especially of the cervix. The peripheral bloodvessels in the mucous membrane (endometrium) are engorged; congestion, thickening and swelling occur, adenoids develop and the pathological picture is the same as in vagotonic states, affecting the segments controlling the mucous membrane of the upper respiratory tract.

TREATMENT.

In treatment, ovary, whole gland, is indicated when hyperpituitarism exists; the stress is thus removed from the pituitary and the high blood pressure is lowered and the vagal stimulation reduced.

When thyroid exhaustion has occurred, as it does in thyroidal types when effort is made to compensate for ovarian deficiency, administration of thyroid gland will often effect results when used alone or it may be necessary to combine it with ovary. In hyperactive thyroidal conditions, frequently seen in the early stages of thyroid overcompensation, administration of ovary will relieve the stress and allow the thyroid to return to its state of normal function.

Exhaustion states following prolonged illnesses, psychic and physical shock reactions such as create suprarenal gland exhaustion, thus causing the vagotonia due to hypoadrenia, are also frequent causes of dysmenorrhoea. In such cases the associated low blood pressure incident to the hypoadrenia indicates that both suprarenal and thyroid gland should be used to raise the lowered sympathetic and thus reduce the vagotonia. In dysmenorrhoea of this origin, the administration of ovarian gland is not indicated as the gonads are not primarily at fault. Upon the proper selection and correct analysis of cases depends the successful outcome of endocrine therapy.

Radium and X Ray Treatment of Hyperthyroidism*

By C. AUGUSTUS SIMPSON M. D.,
Washington, D. C.

It should be recognized that radium and x ray therapy is contraindicated in certain forms of goitre, and in these types a surgical operation is not only the right procedure, but is likewise the only way of curing the patient. X ray and radium are both useless in all forms of goitre that are atoxic and without subjective symptoms. This class may include colloid, cystic, fibrous, calcareous and osseous goitres unless they are associated with and are causing the well known symptoms of hyperthyroidism. Surgery is the best treatment for all enlarged, disfiguring, hypertrophic and simple goitres which are unsightly or produce pressure symptoms.

In young girls, about the time of the establish-

ment of the menstrual period, it is common to detect a well marked enlargement of the thyroid at times associated with rapid pulse, loss of weight and increasing nervousness. Rest, quiet life, giving up of athletic exercises and medical treatment are indicated here. If symptoms continue and if infected teeth are present they should be removed. If tonsils are enlarged, infected or have a history of past inflammation they should be x rayed or if this is impossible excised. Two or three exposures of x ray or radium over the thyroid are all that is required to cure these mild toxic cases.

CLASSIFICATION.

In order to understand more intelligently the indications for medicine, radiotherapy or surgery, it is first necessary to classify the lesions.

*Read before the Clinical Medical Society, Washington, D. C., March, 1921.

The one in vogue at the Mayo Clinic may be taken as an example. Here goitres are classified as hyperplastic forty-two and eight tenths per cent., and nonhyperplastic fifty-seven and two tenths per cent. Of the hyperplastic, ninety-nine and two tenths per cent. are toxic, eight tenths per cent. atoxic.

The pathology, symptoms and especially the radium and x ray treatment of the hyperplastic toxic goitre is what this paper deals with, all other forms of goitre I consider to require strictly medical and surgical treatment.

The pathology of toxic thyroids, whether associated with cystic, fibroid, colloid or calcareous degeneration, presents in some part of the gland either an increased amount of functioning parenchyma or a deficient storing up of the gland secretion, or both. In most cases the secreting capacity of the gland is greatly increased, while the reservoir capacity of the gland is much decreased.

OVERSECRETION.

The oversecretion or too rapid elimination of an iodine compound from the thyroid which may be clinically normal in size gives rise to the symptoms we speak of as hyperthyroidism. To check the oversecretion of this iodine compound by the parenchyma of the thyroid is the object of all medical, x ray, radium and surgical procedures. Nature sometimes accomplishes this by producing a colloid or fibroid degeneration of the gland which encroaches upon and destroys the pathological quantity of the parenchyma, after which the symptoms subside.

Medical treatment does it by sedatives and rest, which decrease the nerve stimulation to the gland. It is evident that this can be accomplished only in a minority of the severe cases or where the symptoms are mild and of short duration. Surgical removal of part of the overactive gland permits the patients no time to adjust themselves to this abrupt and serious shock to the vital forces of the body, a shock that is apparent to any one who does a great amount of thyroid surgery and which can be and is readily recorded by the usual metabolism tests.

EFFECT OF X RAY.

The effect of x ray and radium on the thyroid gland is to produce a striking atrophy and shrinkage of the thyroid parenchymal cells, both on the part of the protoplasm and the nuclei, a condition which produces a marked and very apparent reduction of the secretory function of the parenchymal cells (1). Waters demonstrates the pathological picture as a perfect reproduction of a very atrophic and inactive thyroid gland, such as one sees after a spontaneously cured toxic goitre. In other words, the pathologist reports that the x ray produces a gradual and progressive atrophy of the gland cells which is analogous to and microscopically indistinguishable from a spontaneous and natural retrogression of the disease.

In a certain percentage of cases of exophthalmic goitre an enlarged thymus is present. In an original article published by me in September, 1915, I exhibited a number of microphotographs showing how easy it is to atrophy the thymus glands of rab-

bits and guineapigs, almost all the thymic tissue being replaced by the thickened trabeculae and the enormously hyperplastic capsule. For these patients the x ray offers ideal and superior results to any treatment known. I have two patients who after two and three operations each followed by a return of the tumor and recurrence of all symptoms, in one of acute mania, who are well today after six x ray treatments. Johnston, Greer, Boggs and others have reported such cases.

Since 1914 I have treated over a hundred cases of hyperthyroidism and my results average over seventy-five per cent. of the relief of all symptoms except the exophthalmos. In fifty per cent. of my patients the contour of neck became normal and the tumor disappeared.

Usually the first sign of improvement is a fall in the pulse rate followed by a gain in weight. The nervous manifestations improve, and palpitation of the heart ceases to be troublesome. The ability to work and exercise returns and to all practical purposes the patient becomes normal.

If the patient is seen and treated early in the disease the exophthalmos and other eye symptoms subside, but if the disease is of long duration there is a deposition of fat in the orbit which precludes a cure from either rest, x ray, radium or surgery.

I am firmly convinced that my percentage of cures would have been higher had I been able to select the patients, as some surgeons do, or had all cases been pure examples of hyperthyroidism. Not being an internist, and being interested only in radiotherapy, I accepted the diagnosis of the referring physicians, who were supposed to make a complete physical examination before recommending any treatment. The Goetsch and metabolism tests at this time weed out some of these borderline cases.

TECHNIC.

In undertaking the application of massive doses of x ray for hyperthyroidism as early as 1914 I was much handicapped for the want of a satisfactory technic. No articles had been written or read in America at that time, and I seriously doubt if more than two or three men were treating exophthalmic goitres with any but fractional, small doses of x ray. I was therefore necessarily compelled to originate my own technic. This of course could not be done without some mistakes which I willingly and humbly acknowledge. The mistake I made in my early cases was to hurry the treatments and use filters that were too thin. I have learned to give treatments at intervals of three and four weeks instead of ten days and two weeks; and am today using a two mm. aluminum filter instead of one mm. The anterior and lateral surfaces of the neck being flexor surfaces, are covered by rather thin and, as I have demonstrated, radiosensitive skin so that I never give more than three and a half points Hampsen, the plastile resting on the skin and covered with five layers of chamois skin. With this technic I have had no telangiectasia or other signs of radioirritation.

In bedridden or hospital cases I map out nine areas over each lobe of the thyroid, each area being the size of my thirty M. G. double strength radium applicator. I use three mm. of aluminum and one

layer of zinc oxide adhesive plaster which keeps the radium applicator from shifting. The radium is kept on each area four hours, which requires thirty-six hours to cover a moderately enlarged lobe. A nurse or educated person must be in attendance to change the applicator at four hour intervals, care being taken not to cover the same area twice in four weeks. No burn or scar is produced and one to three treatments will usually relieve the patients of their symptoms.

I have recently had a letter from a young lady of Newport, R. I., who had all the symptoms of a typical but early case of hyperthyroidism relieved by one treatment, using the technic described above.

Probably the greatest advances made in knowledge of hyperthyroidism have been made in the past few years. I refer to the metabolism tests. Clinical symptoms used in the past gave one several valuable signs of thyroid intoxication, but it was difficult in that we had no accurate index to measure exactly the degree of this intoxication and disturbed metabolism. Now we can not only state this degree of disturbance in actual figures, but we at last are in position to say just how much any therapeutic measure has improved the patient. In the face of this test the physician with his hobby, be it drugs, x ray, radium, or the scalpel, is compelled to show his wares. For a complete symposium on this subject I shall refer you to an article from the Massachusetts General Hospital (2). Condensed, it dealt with two series of cases of hyperthyroidism, one treated by x ray, the other by ligation and surgical removal of part of the thyroid

gland. Metabolism tests were performed on both sets of patients five years after the completion of treatments and operations. The actual tests showed that the surgical cases at this time were as well as those who had been x rayed, but it also showed that the cases x rayed were actually seventeen and one half per cent. more toxic than the surgical cases before x ray treatments were begun.

If there remains anyone who honestly and conscientiously wishes to know the real value of x ray and radium in hyperthyroidism, who doubts the ability of the ray to cause atrophy of thyroid gland, or who is the least bit sceptical as to the effects of this atrophy on the internal secretion, body metabolism, and symptoms of hyperthyroidism, let them seek the facts—not hearsay or vague clinical findings. We have and can study the pathological specimens which actually show the degree of this atrophy. We also have the exact figures from the metabolism tests showing the precise degree of improvement in cases of hyperthyroidism during the x ray treatments and five years after completion of the treatments. Figures that prove that massive doses of x ray correctly applied over the thyroid gland offers the patient with hyperthyroidism as much or better hope for cure than any form of therapy known, not excepting surgery.

Some Ophthalmological Implications of Endocrinology

By PERCY FRIDENBERG, M. D.,
New York.

Every advance in our knowledge of the fundamental reactions of living beings to their environment in health and disease accentuates the essential unity and continuity of the organism and the mutual interdependence of its component parts. At the same time, the vital processes such as secretion, and the basic reactions of metabolism, respiration and functional catabolism, are brought into relation with similar reactions in the domain of colloidal chemistry and of physical chemistry. Endocrinology is a step forward from the cellular pathology which looked upon the organism as a histological specimen, and from the narrow bacteriology which considered the body as a culture medium and most disease as an inoculation. In a way, the study of the glands of internal secretion brings us to a reconsideration of some essentially valid facts of the old humoral pathology with its acceptance of individual blood or tissue juice mixtures and dyscrasias to explain personal variations in reaction to diet and drugs, infection and immunity, fatigue and food, as well as to mental and emotional stimuli. The endocrine system, with its relation to the vegetative nervous system, refers to every department of biology; and

the glands of internal secretion influence morphology, heredity, function, and immunity.

The relation of this system to the eye and its diseases is a complicated one. In the first place we have the biological aspect of inheritance, and the influence of race, and of skull form, both largely endocrine, on the shape and consequently the refraction of the eye. Here, too, we think of the origin of pigment from the chromaffin system, and pigment plays a striking part in the structure and in the function of the eye. The eye is in fact the most highly pigmented organ in the body. The retinal changes in vision are practically a dissociation of pigment by photoelectric process and association in the dark and resting. Pigment changes are characteristic of a number of degenerative conditions, some of them typically familial and hereditary, of the light perceptive tissues of the eye. The iris, curiously enough, is the only tissue in which hypernephroma is known to metastasize. The relation of coloring matter to energy is probably a fundamental one which is still a question for experimental biology to solve. The nutrition and normal development of the eye, as of other structures, depends

partly on vitamins, and it is probable that pigment has a certain definite significance in this respect, too. Starvation, improper diet, and even the lack of a single vitamin, notably the fat soluble anti-rachitic vitamin, produces typical ocular disturbances, such as degenerative processes in the cornea, or peculiar visual disturbances, such as hemeralopia. The rôle of hormones and vitamins in ocular development is indicated, further, by the incidence of changes in the cornea and lens, notably cataract, in such typically dyscrinoid manifestations of disordered metabolism as rickets, tetany, and, possibly, pellagra. The retrogression of vital physiological processes accompanying old age is manifested more strikingly in the eye by senile changes such as gerontoxon and cataract, than perhaps in any other part of the body. The marked individual variation in these conditions accentuates the endocrine factor in their causation.

Physiologically, we note that the eye is largely under the double control of the vagus, via the fifth and third nerves, and of the sympathetic. There are several purely ocular reactions which indicate this. First and most important, pupillary reaction and the associated action, accommodation, of the ciliary muscle. This reaction of the pupil to vagus stimulation (sphincter contraction) and to sympathetic irritation (dilator action) has been studied most carefully from its neurological side as well as from the viewpoint of pharmacodynamics. The action of the two main groups of ophthalmiatric alkaloids, the miotics, such as eserine and pilocarpine, and the mydriatics, such as atropine and hyoscine, are typically vagotonic and vagoparalytic, respectively. The pupil has a marked correspondence to the heart beat as an index of emotional stimulation and of the relative dominance of the sympathetic or parasympathetic systems. Broadly speaking, contraction of the pupil corresponds to slowing of the heart, and dilatation, to its acceleration. Intraocular inflammation and irritation are generally accompanied by contraction (vago-tonia) of the pupil, and in but one serious ocular malady, glaucoma, by dilatation. The terminals of the vagus may be influenced directly by pressure on the eye and produce an immediate reaction on the rate of the heart beat, slowing it or increasing the tempo, according to the relative vago-tonia or sympathico-tonia of the subject.

This oculocardiac reflex of Dagnini-Aschner is still a subject of clinical study. Besides the pupil we have winking, tear secretion, and intraocular tension, all of which show a double dependence on the two antagonistic branches of the vegetative nervous system. Vagus irritation appears to inhibit winking, tear secretion, and the entrance of fluid into the eye from the capillaries and endothelium of the uveal tract. The result of the last action is to tend to reduction of intraocular tension. In pathological increase of pressure, narrowing of the pupil by miotics cuts down the glaucomatous tension. Sympathetic irritation stimulates winking and tear secretion, and causes dilatation of the superficial vessels of the eye. The relation of the eye to the orbit is also strikingly affected. Enophthalmos is a sign of sympathetic paralysis, or relative vago-

tonia; and exophthalmos, or prominence of the eyeball, of sympathetic irritation, or relative vagoparalysis. The most dramatic example of the latter complex is in the clinical picture of Graves's disease, an exquisite manifestation of ocular sympathicotonia. The opposite is manifested by the appearance of the eye after injury of the cervical sympathetic, in which we have typical miosis, anhidrosis, ptosis, enophthalmos, and narrowing of the lid fissure. Ocular sympathicoparalysis is indicated, to my mind, by the Argyll Robertson pupil in locomotor ataxia. This reflex pupillary rigidity is largely due to a paralysis of the dilator pupillæ and the consequent failure to react is largely spastic, a failure of the contracted miotic pupil to dilate. In the clinical field, the interrelation of endocrinology and the eye is indicated by facts of infection and inflammation, immunity, and disorders of metabolism. In passing, we notice a series of inflammations involving the cornea in which an element of nerve irritation or injury is invariably active. Such conditions as herpes febrilis, or of keratitis with anesthesia, neuroparalytic keratitis, often occur in association with characteristic disturbances of endocrine balance. Phlyctenular keratoconjunctivitis, but recently hailed and accused as tuberculous on the slender basis of positive reactions to the von Pirquet test, is most probably scrofulous, in the older sense of the humoral pathologists. It is but one manifestation of the exudative scrofulous, or lymphatic diathesis. The others are, tendency to exudations, lymph hyperplasias, urticaria, angioneurotic edema, spasmophile reactions in various fields, indicated by croupy cough, tics and spasms, pylorus cramp, pertussis and asthma, hay fever, frequent, persistent, and recurring head colds. The biochemical basis is an acidosis, associated with marked disturbance of the carbohydrate and fat metabolism. The endocrine factor is probably a relative hypothyroidism due either to repeated infections (bacterial thyrotoxication), heredity, or a morbid dominance of other glands, notably the pituitary. This is indicated in the ocular sphere by the facies of the patient with wide spaced, large, often hypermetropic eyes, broad glabella; by disturbances, such as headache and vertigo, out of all proportion to the refraction error which may be found, and by the beneficial effects of thyrosympathetic stimulation by such drugs as atropine, calcium, and the iodides. Of deeper seated ocular inflammations, those of the uveal tract are important. Syphilitic, tuberculous, gonorrhœal, and rheumatic uveitis were always recognized as the principal categories. We must deal with the factor of dyscrinism in each of these varieties. In addition we have the important group of iritis due to focal infections of teeth, tonsils, sinuses, and intestinal tract, with their implications for disturbances of nutrition and of actual damage to the glands of internal secretion in their immunoprotective faculties. The relation of renal disease and of diabetes to retinitis and to cataract, respectively, is an important chapter on which we merely touch in passing to call attention again to the endocrine factor which runs, like the red thread of the British Admiralty, through all.

Rheumatism and the arthritic conditions, as well as gout, have their well known ocular reactions, in the connective tissues of the eye, conjunctiva, sclera, and cornea, and in the uveal tract as well. The lowered metabolism incident to the basic disease seems to be the most important factor in producing not only the joint and muscle lesions, but the ocular disturbances as well. Certain it is that the removal of infected tonsils and of adenoids seems to be only one of the beneficial factors active in operative treatment. The starvation preceding and following the surgical procedure seems to be of importance, too. A logical conclusion would be that in rheumatic iritis we should cut down alimentation as far as possible, aid elimination, and stimulate the metabolic function of the thyroid. It is noteworthy that many of our empirical procedures act on this tacit assumption and in this way. Thus we explain the good effects of cathartics, alkalines, iodides, massage, heat, and passive motion, to say nothing of atropine. Glaucoma is a condition about which a long chapter could be written. The theories of its causation are largely mechanical and have to do with topographic relations of lens and anterior chamber, the dimensions of the filtration angle, the rigidity of the sclera, the size of the circumferential space, and so on. These factors probably do play an important rôle in providing an anatomical, structural, predisposition. The necessity of another factor has been recognized by the neurotic secretory theories, and the colloidal chemistry view which considered glaucoma as an essential edema on an angioneurotic basis. The endocrine implications are striking. We have to do with a marked and sudden paralysis of the ocular vagus with an equally marked overaction of the sympathetic. This symptom complex comes on at an age when there is a tendency to relative hyperthyroidism on account of the recession of the internal secretion from the gonads. The climacteric, male as well as female, is the typical epoch for glaucoma. Then, it is unusually common in the Hebrew race which has what we call a bad inheritance, sympathetically speaking, as indicated in the incidence of neurasthenia, speech defects, and diabetes.

The emotional element is further indicated by the sudden appearance of an attack after worry, anger, exhaustion, cold, or operation on the other eye. Again, the element of the vegetative nervous system is indicated by our using empirically and successfully in the acute attack of glaucoma, heat and rest, morphine and coffee, dionine and pilocarpine, all of which stimulate the parietic vagus and restore the endocrine reserve. A prophylactic inference would be the advisability of using small doses of vagotonic drugs and of those which may have a sedative action on the sympathetic and the thyroid, perhaps by the administration of antagonistic glands (pituitary, gonads) where there is a racial, age, or individual tendency to high intraocular tension and so to acute glaucoma.

Ocular headache is another topic about which volumes could be, and have been, written. In connection with other manifestations of eye strain, local and reflex, this forms an important part of the oculist's field of activity. It is striking that the

symptoms are often out of proportion to the refraction error, and that rest cures with complete paralysis of accommodation (atropine, cycloplegia) act immediately, although often only temporarily. Correction of the refraction error often gives little relief, and this applies as well to the prescribing of prisms or decentred lenses for imbalance of the extrinsic ocular muscles, for insufficiency of convergence, and so on. The endocrinological implications here are physiognomonic, as well as therapeutic. The patients who tend to eye strain are likely to be brunettes with vagotonic and relative hypothyroid makeup, that is, of a pituitary-adrenal or gonadopituitary type. Their refraction is hypermetropic or astigmatic hypermetropic, the pupils small, eyes recessed, narrow fissure; their general reaction spasmophilic, with cramps all over, sphincter spasms, stomach cramps with acidity, freaks of temper and emotion, attacks of indigestion.

The opposite type of patient comes to us with complaints of asthenopia, that is, of deficiencies, weaknesses instead of strain. Thus rapid tiring in the light, with reading, or sewing on white work, headaches at theatre, the cinema or in art galleries, in a word, retinal asthenopia. These patients are more likely to be blonde, full blooded, wide eyed and with wide pupils, full, vascular lids and conjunctivæ, and prominent eyeballs. The refraction is generally myopic. These patients have, evidently, more than enough of the thyroid principle. They need adrenal, gonad, or pituitary restoration, and drugs to depress the sympathetic system.

The first mentioned, vagotonic, group is materially benefited by atropine systematically as well as locally, and by small doses of thyroid, and many of the peculiar reflex symptoms disappear promptly. The wearing of correcting glasses probably cuts down one source of vagus irritation and the same effect is produced physiologically by rest cures, dark room treatment, and full cycloplegia.

If we study the endocrine markings and manifestations of our eye patients and the ocular symptoms of our endocrine types and dyscrinisms we shall in time be repaid by a better knowledge of the underlying relations between the glands of internal secretion and the eye and its diseases.

38 WEST FIFTY-NINTH STREET.

Qualitative Variations in the Structure of the Thyroid.—G. Vercellini (*Endocrinology*, January-March, 1920) came to the conclusion that in normal conditions the human blood serum has *in vitro* a powerful oxidizing action on hydroquinon, due to a substance soluble in ninety-six per cent. alcohol and thermostable; this power increases a great deal in cases of paresis, and to a less extent in epilepsy—that is, the oxidizing power is more marked during the interaccessual periods, less before the seizure. Owing to the fact that in these two diseases in which cyclic groups with oxybenzolic structure are found, the blood serum offers an increased oxidizing power toward such substances, the author asks if it might not be possible, with this reaction, to recognize *in vivo* the presence of these qualitative thyroid variations.

The Clinical Value of Basal Metabolism Determinations in Diseases of the Thyroid Gland*

By HERMAN O. MOSENTHAL, M. D.,
New York.

The first intimation that the metabolism in exophthalmic goitre was abnormal was given by Friedrich Müller in 1893. He found an increased nitrogen output, and thus demonstrated an excessive protein destruction in this disease. This comparatively simple observation was the starting point for the many experiments and studies that have served to illuminate the problems of hyperthyroidism and hypothyroidism. Upon them the rational principles of treatment have been based. Very recently the methods of estimating the metabolic rate have been simplified a great deal, and it is possible to make rapid and frequent observations of the basal metabolism. These determinations provide what is acknowledged to be the best means of making a diagnosis of overactivity or underactivity of the thyroid gland, and, furthermore, they furnish criteria which guide the surgical, röntgen ray, and medical treatment. By the examination of the figures obtained in determining the basal metabolism in various diseases, the following results will be noted:

TABLE I.

Basal metabolism as reported in various diseases. Percentage above or below average normal. ¹		
Normal	-15 to +15
Obesity	-14 to +10
Diabetes mellitus	-19 to +23
Severe	-19 to +23
After fasting	-36 lowest observed
Emaciated	-37 to -10
Cardiorenal without dyspnea	-10 to +10
Cardiorenal with dyspnea	+25 to +50
Nephritis with edema	-40 to +14
Nephritis without edema	+2 to +29
Pernicious anemia	+2 to +33
Leucemia	+21 to +123
Typhoid fever	as high as +50
Tuberculosis (temperature about 104°)	+15 to +35
Tuberculosis (no fever)	-3 to +15
Prolonged undernutrition	-30 to -10
Exophthalmic goitre:		
Very mild	+15 to +30
Mild	+30 to +50
Severe	+50 to +75
Very severe	over +75
Cretinism and myxedema	-40 to -15

¹ These figures have been taken largely from the publications of E. F. DuBois and his collaborators though other sources have been consulted.

Tuberculosis, cardiac disease, undernutrition, obesity, and certain nervous affections may lead to the suspicion that the thyroid gland is functioning too actively or too little. In the event of necessity of differential diagnosis under these circumstances the determination of the basal metabolism is of great assistance, inasmuch as all of the conditions mentioned vary much less from the average normal basal metabolism than do abnormal thyroid states. Other maladies, such as leucemia, cardiorenal disease with marked dyspnea, or typhoid fever, in which the basal metabolism approaches the intensity of that reached in exophthalmic goitre, may be diagnosed by physical examination and the usual routine laboratory tests without having recourse to the determination of their metabolic rate.

One of the best examples of the diagnostic value

*Read before the Medical Section, of the New York Academy of Medicine.

of the determination of the basal metabolic rate in medicine is that furnished by Peabody, Wearn and Tompkins (1). Of fifty-seven soldiers submitted to them for treatment, principally because of rapid heart action, nervous instability and physical inferiority, a diagnosis of hyperthyroidism was made in twenty-four. The normal metabolic rate exhibited by these individuals disproved the diagnosis. This investigation shows conclusively that nervous patients do not necessarily have a high basal metabolism. Nervousness, tremor, slight enlargement of the thyroid gland, lagging of the eyelids, and tachycardia were present in many of these patients; these signs and symptoms may therefore be considered of minor importance in making the diagnosis of Graves's disease. Bruits and thrills over the thyroid gland, a tachycardia which persists when the patient is at rest, and loss of weight, appear to be of greater significance.

The data obtained in individual cases may possibly serve to illustrate the usefulness of the basal metabolic rate as a diagnostic measure better than generalities. The following is the synopsis of a case referred as one in which it was indicated to determine the intensity of the hyperthyroidism:

CASE I.—A woman, forty years of age, house-keeper. She had been exceedingly nervous and irritable, and her sleep was considerably disturbed. She had complained of sweating, chilly sensations, and hot flushes, during the day as well as at night. She had no reserve strength, and became very easily tired. There had been a loss of weight of twenty-eight pounds in three years. Some dyspnea was present when the patient was quiet, and this was considerably aggravated on exertion. She complained of cardiac palpitation; vomiting and diarrhea had not been manifest at any time. Physical examination showed the patient to be rather thin (weight 110 pounds, with clothes; height, five feet three inches), and very nervous. There was a distinct tremor, a pulse rate of 120 which dropped to 84 on resting. The skin about the face and neck was hyperemic, but was otherwise normal. There was no exophthalmos, no Moebius's or Von Graefe's sign, and examination of the thyroid gland revealed no abnormalities.

After treating her with various forms of therapy, which did not prove to be of value, her physicians were considering the advisability of more active interference with the functions of the thyroid gland; the possible diagnosis of Graves's disease certainly seemed justified. Her basal metabolism proved to be 94.3 per cent. of the normal standard, and, therefore, well within normal limits. Hence this patient's symptoms were not due to hyperthyroidism, and attempts to curtail the activity of the gland, while they might serve to ameliorate some of the complaints, would be likely to play havoc in other directions.

A case which illustrates the difficulty of diagnosing Graves's disease from the history and physical examination alone is the following:

CASE II.—A tailor, a Russian Jew, complained of epigastric distress for two years, and pains in the right lumbar region for one year; all the large joints ached at times. There were frequent and severe headaches; he was very constipated and had never had diarrhea. The thyroid gland was slightly enlarged, but gave no evidence of bruits or thrills. There was a very slight prominence of the eyeballs, but all other eye signs were negative. A fine tremor of the fingers was present; the pulse rate at different times varied between 84 and 120; the hands were cold and blue. The history and physical examination gave the impression that this was a case of nervous instability resembling the instances of neurocardiac asthenia that gave rise to so much discussion during the war. His basal metabolic rate, however, was forty-one per cent. above the normal value. This figure was too high to be accounted for by possible restlessness during the determination or by the slight tachycardia. The inevitable conclusion was that there was a distinct overactivity of the thyroid in this man.

The nervousness, tremor, and suggestive exophthalmos were virtually the only ones of the accepted signs of hyperthyroidism that were present. Why the tachycardia was not constant, why the eye signs were not more definite, why there was no diarrhea, are questions that can be answered in many different ways. However, it brings up the very important clinical fact that many of these cases apparently present a dissociated group of symptoms that render it very difficult at times to make accurate diagnoses or to obtain ideal therapeutic results. Thus we have had one patient who complained of cardiac palpitation after the use of thyroxin and thyroid extract, although her basal metabolism was still fourteen per cent. below normal. In another instance there was marked excitability and nervousness, although other signs indicated hyperthyroidism, and the metabolic rate was 23.2 per cent. below the normal figure.

In this case the administration of thyroid gland had a distinct tendency to produce diarrhea and increase the nervousness without materially affecting the pulse rate, the weight, or the feeling of lassitude. In this patient there had been a complete hysterectomy some years before. The question of the depression of the basal metabolism, through loss of the ovarian function, is suggested by these findings. Janney and Henderson (2) described two similar cases in which the ovaries had been removed. In these the basal metabolism could not be brought to normal, as symptoms of distress, palpitation and rapid pulse intervened even on small thyroid doses.

In occasional instances, the basal metabolism apparently does not serve as an exact indicator of the activity of the thyroid gland. Janney and Henderson report a case with thyroid hypertrophy, tremor of the fingers and tongue, sympathicotonia, moist palms and soles, nervousness, excitability, exophthalmos, Stellwag's sign, rapid pulse on slight provocation, and loss of weight and strength, while the basal metabolism was five per cent. below normal. These authors believe this to be a case of

exophthalmic goitre in spite of the normal metabolic rate. In one of our patients, a very obese, lethargic woman, the basal metabolism proved to be normal. She was given thyroid cautiously and this was gradually increased to the rather large dose of fifteen grains a day, which was maintained for more than six months. During this period the lethargy diminished very markedly, there was some loss of weight, the pulse rate going up only to 80 after exercise, and the temperature continued to be subnormal. The only signs of too large a dose of thyroid substance were excessive perspiration and a headache which came on every one or two weeks. Both of these cases are possible examples of disagreement between what appear to be justifiable clinical diagnoses and the basal metabolic rate. Such occurrences are exceptions, and it is a matter of further study and observation to clear up the exact relationship of such findings.

Clinical signs and symptoms have been sought which would parallel basal metabolism determinations and thus make such estimations of secondary importance. The two criteria most often used are the pulse rate and the weight. Neither of these appear to meet the demands as a measure of the intensity of thyroid activity as satisfactorily as the estimation of the metabolic rate. The conclusions of some of the observers who have worked extensively on these problems are of interest. Sturgis and Tompkins (3) conclude that there is a fairly constant relationship between the resting pulse and basal metabolism; a tachycardia of 90 or higher was associated with a basal metabolism of fifteen per cent. or more above the normal in all but sixteen per cent. of 154 patients with hyperthyroidism; when the basal metabolism came to normal the pulse came to below 90 in seventy-eight per cent. of the cases; the pulse rate gave an accurate idea of the course of the disease compared to basal metabolism in eighty-five per cent.; the fact that a pulse rate below 90 during complete rest is seldom, and below 80 a minute is rarely associated with an increased metabolism, is of practical importance in the recognition of a group of nervous patients whose symptoms resemble those occurring in hyperthyroidism.

Means and Aub (4 and 5) draw conclusions that vary somewhat from those of Sturgis and Tompkins. They find that the pulse rate is not an index of the absolute degree of thyroid intoxication, but that the pulse rate does furnish a relative index in the same patient seen at different times; that is, as the basal metabolism rises or falls, the pulse rate in the same person increases or diminishes proportionately, but a given pulse rate is not an indication of a corresponding basal metabolic rate in different individuals. In making comparisons between the pulse rate and the basal metabolism, they use a standard by which pulse rates of 50 and 150 are equivalent respectively to a normal metabolic rate and to a rate 100 per cent. above normal. On this basis there are two types of hyperthyroidism: type I, in which the pulse rate is ten or more above the metabolic rate, and type II, in which it is ten or more below; type I, that with the more marked tachycardia, does equally well on being treated with x ray or surgery, while type II apparently gives poor results with immediate resort to surgery, but does better with

preliminary use of x rays. From the conclusions and the experience with tachycardia which any clinician has at his disposal, it is safe to say that from a diagnostic point of view the pulse rate is not as reliable a diagnostic sign as the metabolic rate.

The only other symptom which has been proposed as a measure of the intensity of thyroid activity or progress of thyroid disease is the loss or gain in weight, and here the comparisons with the metabolic rate are very far from being absolute criteria of one another. Thus Means and Aub find a reciprocal relationship between the weight and basal metabolism in only twenty per cent. of their cases.

The basal metabolism furnishes the best measure by which to gauge the effect of medication, x ray or operation. Most of the published results indicate that this is a simple matter. A closer study of many of the tables, however, shows that the final cure can only be accomplished after months of effort. The metabolic rate is the only test that gives a satisfactory answer to the difficult question whether the activity of the thyroid needs further curtailment or whether thyroid medication should be increased. The following instance may possibly accentuate this point:

In April, 1919, a young woman of twenty-eight had the right lobe, isthmus, and part of the left lobe of her thyroid gland removed. Before the operation her basal metabolism was thirty-four per cent. above normal; after the operation it dropped to twenty-four per cent. above normal; one year and seven months after the operation the metabolic rate had almost returned to the preoperative level, being thirty-two per cent. higher than the average normal. Hence, in this case, the nervousness, tachycardia, etc., which persisted in spite of the operation, were not due to nervousness, as it was tempting to assume,

but to overactivity of the remnant of the thyroid gland.

The value of basal metabolism in diseases of the thyroid gland may be compared to that of hemoglobin in the anemias. In many cases no hemoglobinometer is necessary to determine the grade of anemia existing; in some instances, on the other hand, inspection of the skin and mucous membranes is very deceptive. The proper laboratory test gives us, in both conditions, a correct orientation as to the intensity and nature of the process. It is obvious that in a disease whose treatment involves the permanent interference with vital functions, by surgery or x ray, such a test as basal metabolism furnishes an indispensable factor in judging whether the activity of the thyroid gland is normal, increased or diminished, in forming an accurate estimate of the intensity of the disturbance, and finally in guiding the administration of thyroid preparations, the use of sedatives, rest, x ray, or surgery. The fact that many cases may be diagnosed without the aid of this test of precision is no reason to neglect it as some clinicians seem to be desirous of doing. It is a great satisfaction to have a means at hand by which at least one disease in the field of endocrinology may be robbed of its mysticism and exaggerated prevalence, and be properly diagnosed and treated.

Basal Metabolism and Endocrine Manifestations*

By A. S. BLUMGARTEN, M. D., F. A. C. P.,
New York.

Associate Attending Physician and Chief of the Department of Endocrinology, Lenox Hill Hospital.

The importance of endocrine study does not lie in the appreciation of the well known endocrine syndromes. If endocrinology has done anything for medicine at all, and many of us believe it has done a great deal, it has taught the clinician to be a better observer and has broadened his outlook. It has added to his attitude of merely looking for extraneous factors in disease, a better appreciation of the patient's reaction. Heretofore medicine consisted largely of the recognition of anatomical change in organs, and a patient who did not present such morphological evidence was considered unworthy of the clinician's serious attention.

The appreciation of the relation of the endocrine system to medicine is gradually developing what we might term physiological medicine or the study of

the changes in the physiology of the patient as the result of his contact with extrinsic factors, such as bacteria and other irritants. On the other hand, the abnormal physiology may be the expression of a discord between the patient and his environment. This conception of clinical medicine does not abandon the appreciation of pathology, but it aims to recognize abnormal physiology as well. Indeed, both usually occur together, but abnormal physiology may precede the establishment of a lesion or the lesion may not be recognizable by our present methods, which are relatively gross at best.

In such a conception, function plays an equal part with structure, and the so-called functional diseases assume the same importance as the organic diseases. Clinically we can appreciate the rôle of the endocrine system in medicine in several categories:

*Read in part at a meeting of the Lenox Hill Hospital Clinical Society, February 11, 1921.

1. The definite endocrine syndromes may manifest themselves in minor forms; the so-called *forme fruste*. Consequently they frequently pass recognition and mask as various visceral diseases.

2. A definite endocrine syndrome may begin with various visceral symptoms and the identifying symptoms may only appear later. Here, too, a lesion or functional disturbance of the viscera to which the symptoms are referred is diagnosed.

3. The various symptoms of a definite endocrine syndrome may differ in the intensity with which they dominate the clinical picture. Consequently the condition is not recognized unless the entire clinical picture is taken into account.

4. The definite endocrine syndrome corresponding clinically to any of the groups described above may be merely a symptom; the expression on the part of the patient as the earliest manifestation of a well known disease, such as tuberculosis for instance. It is well known to any experienced clinician that tuberculosis may begin with emotional upsets, tachycardia, fine tremors and loss in weight. In addition to these symptoms there may be associated gastric symptoms which may even dominate the clinical picture; and at this time no cough and no physical signs are present to indicate the arising infection. Other infections may be initiated in the same way. Only later when the infection is full fledged can we correlate the entire clinical picture into one etiological entity.

To my mind these early symptoms—in tuberculosis, for example—are really part of a hyperthyroidism, but a symptomatic hyperthyroidism. It is well known that the endocrine system, notably the thyroid and adrenal, plays an important rôle in immunity. This clinical evidence of a hyperthyroidism, therefore, is really the clinical expression of activation of the immune processes. At this time the exciting cause may not be apparent until it overcomes the immunological effort and establishes a recognizable lesion.

5. The careful study of the patient himself in various diseases, from a morphological, physiological and psychic point of view, seems to indicate that individuals suffering from the same disease have characteristics more or less in common. This is also true of normal individuals who react to environment and the exigencies of life in the same way. Now, since the endocrine system is responsible for growth and development, and since we know that each endocrine gland plays its own peculiar rôle in the development and growth of specific structures as well as in the physiology and psychology of the individual, we can group patients and individuals into characteristic types. These types show individual structural, physiological and psychic markings, indicating the domination of one or more endocrine glands, and are called tropisms, such as adrenotropes, thyrotropes, pituitotropes, and pituitogonadotropes. While these tropisms frequently do bear a relationship to susceptibility, this susceptibility is not necessarily specific.

The endocrine gland which dominates the endocrine physiology is naturally more highly sensitized than the others. Consequently it is more subject to injury, with resultant functional deficiency, dis-

turbance in endocrine balance and compensatory phenomena. This injury may be an infection or it may be a disturbance in the relation between the nervous system and the endocrines. For example, in adrenotropes adrenal insufficiency develops in infections and otherwise, more commonly than in others. In thyrotropes, hyperthyroidism develops, and so on. I have seen the most classical case of adrenal insufficiency recently in an adrenotrope, following an attack of scarlet fever.

To determine the various phases in which the endocrine system presents itself in various medical conditions we have to rely as yet largely on clinical grounds. And since, as I have attempted to indicate above, this rôle rarely presents itself as a frank syndrome the actual difficulty of establishing evidence of an endocrine disturbance, causative, associated or otherwise, is multiplied. Nor should we minimize the value of good clinical observation. Laboratory methods have come and gone while many clinical observations have persisted for centuries. I have paid a great deal of attention in recent years to the newer work on blood chemistry in chronic nephritis. Yet the classification and clinical facts established by Dr. Delafield some twenty-five years ago have not been altered. The only difference is that we speak in different terms. Dr. Delafield spoke in terms of clinical data while today we speak in terms of blood chemistry. But the facts established by the clinical data run parallel with the more measurable facts obtained by chemical analysis of the blood.

Nevertheless, the conservative physician's skepticism is justified in accepting evidence of thyroid deficiency, for instance, on the basis of a few scanty hairs on the eyebrow or an evanescent drowsiness or evidence of a dyspituitarism on the basis of a mild adiposity and slight genital atrophy. The burden of proof is on the endocrine enthusiast and he should not permit his feelings to get the better of his reason. Consequently no one is hungrier for exact methods of determining endocrine disturbances than the endocrinologist himself.

At the present time the most exact method for determining certain endocrine disturbances is the study of the basal metabolism. I shall therefore review briefly the salient facts that have finally placed this exact method on a practical basis. It is well known that the metabolism of an individual is variable according to many factors, such as muscular exercise, psychic activity, sleep, digestion, age and sex. It has been definitely established, however, that the level of an individual's metabolism while at rest and after twelve to eighteen hours' starvation is constant, varying only with certain determinable factors. This is known as the basal metabolism. This varies only with the sex, age, and as Rubner has shown long ago, with the body surface. Dubois has worked out certain linear formulæ for the determination of the patient's body surface from his weight and height. Aub and Dubois have thus been able to work out certain normal figures for the basal metabolic level for various ages and for both sexes.

By measuring the rate of oxygen intake and multiplying this by the caloric value of a litre of oxygen

at the respiratory quotient, which is the ratio of the quantity of oxygen consumed to the quantity of carbon dioxide eliminated, we determine the patient's basal metabolic level.

In some of the apparatus the determination of the basal metabolism has been simplified, so that it can be determined by measuring only the oxygen intake, and then figuring the basal metabolism according to the tables of Dubois. This is possible because the caloric value of oxygen is not very much affected by varying the respiratory quotient, and by assuming 0.82 as the respiratory quotient, a figure which has been found to be the average of a large number of determinations. The recent development of a number of practical indirect calorimetry apparatus such as the Benedict, the Jones, and others, has placed the basal metabolism determination on a practical basis. When these apparatus become still more simplified the determination of the basal metabolic level will be just as simple as a blood pressure reading.

Since the basal metabolic level is constant for the age, sex and body surface of the patient, any variation from this level is of pathological significance. We know, however, that the endocrine glands are the chief regulators of metabolism; consequently, any significant change in the patient's metabolic level in the absence of fever (which causes an increase) is indicative of a disturbance in some of the glands of internal secretion. Numerous observers, notably Plummer, McCaskey, Tierney and others have reported changes in the basal metabolic level in some of the well known endocrinopathies. We may summarize their results briefly as follows:

1. In hyperthyroidism the basal metabolic level is raised in proportion to the clinical intensity of the condition.

2. In myxedema the basal metabolic level is diminished in proportion to the clinical intensity of the case.

3. In dyspituitarism with adiposity the basal metabolic level is slightly diminished.

It is not my object in this paper to add my basal metabolism determinations in the frank endocrine syndromes to the cumulative evidence, as they merely corroborate the findings of others. I wish, however, to present a number of cases to indicate the clinical value of basal metabolism determinations as an aid in establishing an endocrine phase in a number of common medical diseases in which we had reason to suspect such a relationship from a careful study of the subjective and objective clinical findings. I am reserving for a future paper, however, a more extensive study of a large volume of similar cases. The basal metabolism readings were determined by the Jones apparatus.

The patients herein reported, suffered from various common conditions in which an endocrine phase was manifest either as a *forme fruste* as a masked frank endocrine syndrome, as a symptomatic endocrine syndrome or as a tropism with injury of the dominating gland.

We must not rely, however, on the basal metabolism determination nor on the clinical findings

alone, but on the proper combination of both. But since the basal metabolism is determined by a more or less exact and measurable method, it is perhaps more reliable.

CASE I.—M. B., a married woman forty-one years of age, came under observation in October, 1920, complaining chiefly of pains in the spine, particularly in the lumbosacral region and in the neck. Chiefly on account of the pains in the lumbosacral region a hysterectomy was done about two years before. I could not determine what the pathology of the uterus was at the time it was removed. At any rate the symptoms did not improve after the operation and similar pains developed in the arms and legs. About ten months ago the patient began to notice occasional slight puffiness of the eyelids and epigastric pain bearing no relation to meals. At times she felt drowsy in the afternoon and was always tired. Her skin was dry and scaly and her hair fell out at times. She rarely perspired. Except for measles in childhood and a rather indefinite attack of rheumatism about twelve years ago, she had never been ill. There was nothing in her family history or in her habits that was relevant or of etiological value.

The patient was a rather stout lethargic middle-aged woman of medium height. Her skin was dry and somewhat scaly; there was no rash on the skin, no pigmentation, and no Sergent's line. There was no general glandular enlargement. The scalp was covered by a rather abundant growth of hair but was full of dandruff. The eyebrows were rather thin in the outer half. There was slight edema of the eyelids. The corneae were dull and listless, the pupils were round, equal, and they reacted to light and accommodation; there was no exophthalmos. The nose and ears showed no abnormal changes. The teeth were in poor condition, and there was a purulent secretion from the sockets. The thyroid was not readily palpable, but was present. There were no supraclavicular fat pads.

The chest was normal in shape and contour; the expansion was good; the breasts were small. The lungs and heart were normal; the pulse was 64, the blood pressure systolic 110, diastolic 90, and there was no evidence of arterial thickening. The abdomen was not distended, the abdominal wall rather thick, no signs of fluid, and no tenderness or rigidity. The abdominal viscera were normal. There was considerable tenderness on pressure in the lumbosacral region of the spine and there were fat pads on either side of this region. There was tenderness along the cervical spine.

The extremities showed slight puffiness of the ankles; there was marked tenderness on pressure over the muscles of the arms, and movements of the shoulder joints elicited marked pain. Vaginal examination showed a stump of a cervix and rectal examination showed only a few hemorrhoidal tabs. Examination of the nervous system showed no evidence of any organic nervous disease.

Laboratory examinations: The urine showed a specific gravity of 1.024, acid, no albumin, no sugar, no indican; microscopically no casts, only a few epithelial cells. Blood examination showed the

red blood cells 3,800,00, hemoglobin eighty-five per cent, white blood cells 9,000; polynuclears forty-six per cent; small lymphocytes thirty-two per cent.; large lymphocytes twenty-four per cent.; Wassermann reaction negative. Goetch test was negative (absolutely no reaction). Vagotonic test was negative. Basal metabolism was -22 per cent.

There was no evidence of any organic disease in this patient. The slight puffiness, the rather dry scaly skin, the lymphocytosis, the dull listless condition, and the scanty hair on the outer eyebrows suggested thyroid deficiency which was corroborated by the minus twenty-two basal metabolism. Since we have objective evidence of thyroid deficiency, it is logical to explain the symptoms in the joints on this basis. The lesion is probably an infiltration into or around the joints.

The patient was put on small doses of thyroxin and within two weeks the pains had disappeared and about three weeks later the puffiness around the ankles had disappeared. She is now alert and active and the basal metabolism test taken about the middle of January was -4 per cent.

CASE II.—F. E., a young girl of about twenty-five came under observation in July, 1920. About two months ago she began to have crying spells and general emotional irritability without any apparent cause. She had become exceedingly nervous, was unable to sleep, had developed persistent pain in the right hypochondrium after meals and was constantly losing in weight. She had no cough, no expectoration, and no temperature.

About four years ago she went to Saranac on account of an early pulmonary tuberculosis which began rather acutely with a severe hemoptysis following an attack of bronchopneumonia. Several months before this she had gastric symptoms similar to the present on account of which she had her appendix removed. She had scarlet fever and measles in childhood and her tonsils were removed when she was ten years of age. There was nothing in her habits or family history that was relevant to her condition. Her father, who came with the patient, was apparently an adrenotrope.

The patient was a rather thin young woman, five feet one inch in height, weighing ninety pounds, temperature normal; no rash on the skin, no pigmentation, and no Sergent's line. Her face was slightly flushed and she blushed frequently and readily. The scalp was covered by an abundant growth of lustrous hair. The features were thin and delicate; the nose was thin, the corneæ were bright. The pupils were round, equal, and reacted to light and accommodation; there was no exophthalmos. The teeth were pearly white, in excellent condition. The tonsils were absent and throat congested. The thyroid was palpable but not enlarged. The chest was normal in shape and contour; expansion was good and the costal angle acute. The lungs showed evidence of a small healed spot in the right apex which showed no physical signs of activity. The heart was normal except for a slight tachycardia. The pulse was 100, the blood pressure 110 systolic, 80 diastolic. The abdomen was not distended; there was slight tenderness on pressure in the right hypochondrium. There was a marked ptosis of the stomach; the lower border extending

to the level of the navel. The other abdominal viscera were apparently normal. The extremities showed a fine tremor of the hands.

Laboratory examinations: Several sputum examinations were negative for tubercle bacilli. Examination of the urine showed specific gravity to be 1.006, acid, no albumin, no sugar. Microscopically, no casts; only a few epithelial cells. Blood count: Hemoglobin, eighty-five per cent.; white blood cells, 10,500; polynuclears sixty-five per cent.; small lymphocytes, twenty per cent.; large lymphocytes, fifteen per cent. Gastric analysis after an Ewald test meal showed free hydrochloric acid four, total acidity fourteen, and a few well digested starch granules. Goetch test moderately positive. Vagotonic test negatives. Basal metabolism $+26.5$.

This patient was under constant observation and her chest was examined repeatedly. About two months after she first came under observation, râles developed around the border of the old lesion in the lung, and tubercle bacilli were found in the sputum. The patient was suffering from emotional irritability, nervousness, tachycardia, gastric symptoms and loss in weight. This clinical picture constitutes a mild hyperthyroidism. This is corroborated by the positive Goetch test and the increased basal metabolic level. In view of the fact that she had an old healed tuberculous lesion in the right apex and that this lesion began with somewhat similar symptoms, it is rational to consider this hyperthyroidism as a symptomatic hyperthyroidism. It may be considered as an early indication of activity of the old process, although the lesion itself did not show any signs of activity until two months later. The rôle of the thyroid and adrenal in immunity is well known, and the overactivity of the thyroid in this case is really the expression of an effort to overcome an arising infection.

CONCLUSIONS.

1. Endocrine manifestations occur in common medical diseases other than the frank syndromes in several forms: a, as a *forme fruste*; b, as a visceral disease in which the endocrine phase is masked by the visceral symptoms or as the earliest manifestation of the frank syndrome; c, as the earliest manifestation of a systemic infection; d, as an endocrine tropism with functional insufficiency of the dominating gland.

2. The recognition of these endocrine manifestations in various common diseases has heretofore been based largely on clinical grounds.

3. Since the basal metabolic level is raised in thyroid overactivity and lowered in thyroid deficiency, we can use the determination of the basal metabolic level as an aid in determining the presence or absence of thyroid overactivity or deficiency in various common diseases which show such clinical signs.

4. A number of illustrative cases are presented in which endocrine disturbances in common medical conditions are determined by means of the basal metabolism determination, in conjunction with the clinical signs.

Three additional cases were reported by the author, one of migraine attacks with evidences of thyroid deficiency, one of mild hyperthyroidism with dominant gastrointestinal symptoms and one that of an adrenotrope with adrenal insufficiency and gastric symptoms. These case reports will appear in full in the author's reprints.

The Relation of Endocrine Disturbance to Tinnitus Aurium*

By J. COLEMAN SCAL, M. D.,
New York,

Assistant Adjunct, Otolaryngology, Beth Moses Hospital; Assistant Ear, Nose and Throat Clinic, Beth Israel Hospital.

Internal glandular secretions, their activities and deficiencies, constitute the most important question in internal medicine at the present time. In this connection I have made a special study of tinnitus aurium, with such remarkable results that an early report is warranted.

In reviewing tinnitus aurium we find it is a condition in the auditory apparatus in which pathological sounds varying in type and intensity are produced. It is one of the most distressing affections, especially when the noises are loud and continuous. The sounds may be experienced as whistling, buzzing, hissing, blowing, ringing, or roaring. They may be intermittent or constant, high or low pitched and may vary from a very mild to a very distressing condition. These noises are increased by menstruation, pregnancy and lactation.

The origin or cause of this condition has never been understood. Most writers attributed it to either an interference with sound waves due to tubal obstruction or to the interference of the sound perceiving apparatus. Other given causes are tubal catarrh, chronic otitis media and auditory nerve irritations. It also exists in otosclerosis and toxemias of various types, or may be due to overindulgence of the sexual function or intoxicants. All writers agree that this condition arises from a stimulation somewhere in the auditory tract, either peripherally or centrally and either direct or reflex. Cases are reported where the agony and insomnia from these continuous noises were so intense that they drove the unfortunate victims to suicide.

The previous treatment of tinnitus aurium was most unsatisfactory. Most methods consisted of inflating the Eustachian canal, its dilatation with bougies, massaging the drum and ossicles with a Seigle's otoscope, the application of electricity, etc.

The success of the treatment of tinnitus aurium by glandular therapeutics depends upon the condition being a symptom resulting from gland exhaustion, or due to a deficient activity of the adreno-thyroid apparatus. The extract of a gland organ will exert an exciting influence in the same organ so that a sluggish gland can be prodded into activity to a degree quite beyond belief and result in a glandular readjustment. The thyroid gland is undoubtedly largely responsible for the distressing symptom of tinnitus aurium. This can be explained by a thyroid deficiency causing a generalized infiltration in which cellular growth and oxidation is interfered with throughout the body. When this infiltration affects the auditory apparatus we get the characteristic symptoms of tinnitus aurium without any definite ear lesions. Sajous describes this as an anemia of this special sense organ, accounted for by the low blood pressure present, as well as by the poverty in the oxidase, its oxidizing principal, causing impairment of hear-

ing and tinnitus. According to Gake, adrenal insufficiency is a potent cause by producing either anemia and mental fatigue or congestion of the labyrinth.

In a series of sixty cases in which tinnitus aurium existed without any disease of the ear, thyroid extract was the routine gland substance administered. A quarter to a half grain three times daily was given, and the patient watched carefully for symptoms of overdosing. Some patients reported improvement on the third day and others at the end of a week. About seventy per cent. of the patients responded to thyroid. Some of these were free from ear noises in two months, others improved greatly and continued calling at the clinic regularly with the hopefulness of being relieved entirely. In ten per cent. of this series of cases thyroid either had no effect at all or else improved them but slightly. In such cases adrenalin substance total gland, two grains three times daily, was given. This produced marked amelioration of the symptoms, but not as quickly or completely as thyroid.

From ten to twenty per cent. of these cases did not respond to glandular treatment. These patients were the very old chronic cases which have been coming to the clinic for the past ten years. One male, aged sixty, obtained relief at first with orchitic substance, but this was only temporary, and further treatment with internal glands proved futile. This can be accounted for by a degenerative process of the ductless glands due to old age and resulting in an autointoxication.

Ovarian extract in five grain doses, three times daily, was tried in several cases, with good results. One patient reported the return of her menstrual flow to normal, with the cessation of her tinnitus aurium, and had been free from this condition for two months. She had given a history of her menstrual flow becoming irregular and scanty with the onset of the tinnitus.

The results of these experiments warrant further study on this subject in its relation to all functional nasopharyngological conditions. The future treatment of functional disturbances depends upon the interest of the medical profession in internal secretory glands. Otolaryngologists will do well to study endocrine disturbance in relation to tinnitus aurium.

Organic diseases will not respond to endocrine treatment which will only affect functional disturbances. The theory is to encourage the overworked glands and to reestablish their normal functional activities. This treatment is of no use in tinnitus due to otosclerosis or to labyrinth or auditory nerve lesions, or to faulty nerve centres.

In conclusion, the possibility of not having persevered long enough should be taken into consideration as a factor in accounting for those cases in which there was no improvement with this treatment.

*From the Otolaryngological Department, Beth Israel Hospital.

Progressive Systemic Deafness as an Endocrine Syndrome*

By JAMES G. CALLISON, M. D.,
New York.

According to present teaching, patients with progressive deafness and tinnitus are to be placed in one of three categories, chronic catarrhal otitis media, otosclerosis, and nerve deafness. Briefly, these conditions may be defined as follows:

Chronic catarrhal otitis media is that condition in which there is an increase in the time of bone conduction of sound and a decrease in air conduction, a raising of the lower tone limit, and increasing deafness. Tinnitus aurium may or may not be present. Otosclerosis is characterized by advancing deafness, extreme tinnitus, a wide open Eustachian tube, no change in the drum membrane, absence of secretion in the external auditory canal. Paracusis is usually but not necessarily present. In nerve deafness the upper and lower tone limits are narrowed, the relationship between bone and air conduction is not at all or only slightly altered, and there is progressive deafness, usually rapid.

The term otitis media, as applied to these conditions, is open to serious objection. It supposes two wrong inferences. One is that the condition is primarily a local change, and the other that it is inflammatory in nature. The condition is really the local manifestation of a systemic disturbance, and the change is partly infiltrative and partly a lack of tone, or relaxation due to degenerative changes, in tissues with a purely mechanical function. In some cases the infiltrations and in others the relaxation will predominate in the local changes.

The use of the term otosclerosis to separate the terminal stage of a case of progressive systemic deafness from its earlier manifestations is not justified. In this particular instance the disease has commenced in early life, usually at puberty or adolescence, before ossification is complete, and the course of the disease has been a stormy, rapidly progressive one. The term nerve deafness similarly separates off the group of cases of progressive systemic deafness in which the infiltrations and degenerations are mainly in the nervous mechanism concerned in the act of hearing. In each case, there seems little justification for creating separate entities for the conditions. Attributing them to a systemic disturbance based on a pluriglandular dyscrasia correlates the symptoms in a rational way, making their etiology definite and concrete, and puts their treatment on a physiological basis. The systemic evidence of this pluriglandular dysfunction accompanying progressive deafness, whether in a causal relationship or not, is present in all the tissues and organs of the body. This includes the blood and vascular system, the skin and its appendages, the digestive tract, the nervous system and the genitourinary system. In many instances the changes in other parts of the body are more marked than in the ears themselves.

The general aspect of these patients is that of age.

This may be in actual years, or they may be aged beyond their years. This is particularly true when the condition is encountered in early middle life. The hair is gray beyond their years, is dry, lustreless, and may be falling out. The skin is wrinkled and dry and chaps easily. The eyes are dull and expressionless. The glandular secretions generally, so far as can be observed, are disturbed and less abundant. These patients are overdressed for warmth, even in summertime, and they stand winter weather badly. Mentally, they are apathetic and lack interest. They are rarely in a hurry, tire easily, and sleep badly, and yet may be drowsy during the day, especially after a heavy meal. Constipation is nearly always complained of, and in women, there are menstrual disturbances. Generally, they appear to lack the thing we call "pep." Their energy is at a low ebb.

Blood and vascular system.—The cardiovascular system usually lacks tone. The blood pressure varies, but is inclined to be low in uncomplicated cases. It is not unusual to find it between 100 and 115 millimetres, and it may be below these figures. The pulse pressure varies and is not constant, but is more inclined to be low than high. Sometimes the blood pressure is high. This has been encountered three times in the series of cases studied, twice in the female and once in the male, and has been associated with the menopause period in all cases, occurring during the change or after it is complete. It is of the type spoken of as functional high blood pressure, and there is no reason why conditions other than the menopause should not bring it on. Arteriosclerosis does not seem to be present in many of the patients treated for progressive systemic deafness. The pulse is sometimes slow and the temperature below normal. These patients may complain of cold hands and feet, and they stand the cold badly. The lack of pressure, the anemia, and the infiltrations in the skin prevent proper warming and nourishing of the extremities.

The skin and its appendages.—The glands of the skin, sebaceous, ceruminous and sweat, are suppressed or sluggish in their action. As a result, the skin is dry and the patient perspires but little. There is, in advanced cases, a lessening of the cerumen in the external auditory canal. These patients come into the office or clinic on warm days with heavy clothing on, and yet there is no evidence of perspiration. The skin is frequently loose and flabby in texture and not healthy in appearance. Sometimes there is excessive subcutaneous fat, and the skin may then assume a myxedematous hue. The hair is inclined to be dry and brittle and is usually falling out. When the thinning of the hair is far enough advanced to be noticeable, it is most advanced at the hair margins. The hair over the forehead has receded, and at a later time the other hair margins may show the change. The hair and beard lose their pigment and turn gray. This gray-

ness is usually more advanced than the years of the patient would indicate. The eyebrows are inclined to be thin, especially at the outer third, where the absence is very marked. This thinness of the eyebrows may have always been present, or the eyebrows may be falling out. The body hair is usually scant in the male.

The teeth are nearly always decayed. It is a common remark in the clinic that these deaf patients do not come for treatment until they have paid all their money to the dentist. The reason for this lies in the fact that the decay of the teeth antedates the onset of deafness. The decay attacks both crowns and roots of the teeth, but the crowns seem to suffer most, as the roots are frequently retained. Apical abscesses are common, both in these retained roots and in apparently healthy teeth. There are exceptions to this observation that the teeth are decayed, but this class with good teeth are rare and are in a group by themselves. They are mentioned here only to exclude them from the general class under discussion. There is a tendency for the teeth to be crowded, if enough of them are still present to judge on this point. In addition to the decay of the teeth, many of these patients also suffer from pyorrhœa alveolaris. This is not so universal, however, as the early decay of the teeth. The gums may be receding, or they may be red and inflamed and at the level of the dental interstices continued in polypoid prolongations.

Gastrointestinal tract.—Constipation is the rule. A large proportion of the patients with progressive systemic deafness are so habitually constipated that they have already adopted some favorite method of caring for the condition. The constipation is due to a lack of tone in the intestinal wall, together with a lack of the proper quantity of the secretion of the intestinal and adjacent glands—succus entericus, bile and pancreatic secretion. There is, with this lack of tone of the intestinal wall, an enteroptosis and the intestinal loops lie low in the abdominal cavity. A general ptosis of the abdominal contents may be present. There is, accompanying the constipation, proteid decomposition and toxic absorption from the intestinal tract. The most important of these toxic substances are the amino acids.

Genital system.—In women the menstrual cycle is generally out of order. The disturbance may be irregularity as to time, but seems to be more often than otherwise a reduction in the amount of the menstrual flow. This reduction, when not amounting to complete amenorrhœa, may require careful questioning to bring out the fact. Each woman seems to think, if there is no excessive departure from the normal, that her menstrual condition represents that normal. I recently had a patient assure me that her menstrual cycle was quite all right, and yet on questioning she admitted that she only used two napkins for her whole menstrual period. Menstrual backache may be complained of when there is no abnormality in the uterus. It is due to infiltration and toxic degeneration in the sacrolumbar and coccygeal joints. In men the sexual measure is more difficult to obtain, as there is no specific act by which it may be judged. I am, however, under

the impression that there is some suppression of the sexual vigor.

Bones and ligaments.—There is some increase in the elimination of both calcium and phosphorus in the urine, an increase greater than any change in the temporal bone can account for. The pathological discussions on the bone changes in the various stages of progressive deafness fail to compare the temporal bone changes with those in other parts of the body. There are undoubtedly changes in the temporal bone in the way of faulty deposition and absorption of calcium and phosphorus. But whether there is a general change in the bony framework of the body has not been determined, except as may be anticipated from the amount of calcium and phosphorus eliminated in the urine. As the bony metabolism of the body is under unit control through the blood, with some influence from the trophic nerves, there is every reason to think the bone changes are universal. This would account for the blood calcium changes observed in the advanced cases that have come to be called otosclerosis. These changes consist in faulty deposition and absorption of bone salts, with a cellular infiltration in the Haversian canals and along the vascular spaces.

As to the ligaments, there is no doubt as to their undergoing certain changes. There is a general lack of tone, in the ear as well as throughout the body. If the condition had its inception in early life, these patients may be of the double jointed class. If the inception was in later life, the change will consist in infiltration and thickening. That there is a tendency for the ligaments to relax under strain is evidenced by the number of these patients who suffer from flat feet of varying grades. This lack of tone in the connective tissues generally is to be expected from the pathological changes present in the glandular dyscrasias responsible. It also explains the relaxation of the drum membrane.

The nervous system.—The memory is frequently bad in these patients. They are not mentally active, and lack concentration and mental persistence, and the disposition may be irritable. They have such a list of ailments that it is frequently difficult to control them in history taking, once they are launched on a full recital of their bodily ills. Some of them are phlegmatic, but the rule is for them to assure you that they are very nervous, and this covers a large variety of indefinite conditions. These patients are frequently classed as neurotics and no attention paid to the story of their ailments. They are slow in their responses, mentally and physically. In applying the hearing tests they reply with the utmost deliberation, even when they hear the given sound well, and they use the same deliberation for physical movements during the course of the treatment.

These patients come to the otologist complaining of progressive deafness and head noises, one or both. There is no constant quantitative relationship between these two symptoms. The deafness may be extreme and no head noises present, or the tinnitus may be almost unbearable with a very slight depression in the acuity of hearing. On examination the changes in the drum membrane and

in the middle ear are equally inconstant. The drum membrane may show extreme retraction with full acuity of hearing, or the drum may be in its normal position, with advanced deafness. Likewise the drum membrane may be very thick or very thin, with no quantitative relationship to the symptoms of which the patient complains. In the same way, the relationship between the condition of the drum membrane and the Eustachian tube is equally inconstant. The drum may be retracted and yet the Eustachian tube, on inflation, seem to be wide open. On the other hand, the Eustachian tube is sometimes found well closed by the swelling of the mucous membrane, and yet the drum is but little retracted. To put this in the form of a practical statement, the local speculum examination helps but little in making a diagnosis. The functional examination of the ear throws more light on the condition with which we are dealing, and yet the picture is inconstant—hence the varying diagnosis of chronic catarrhal otitis media, otosclerosis and nerve deafness. There is, however, a fairly constant relationship between the length of time the condition has been present, the severity it exhibits, and the functional examination. There is present both a disturbance of the transference or conduction of the sound waves and a failure of the sounds to register—a dulling of the perception apparatus. These symptoms, the changes in bone and air conduction, and nerve perception are too well known to require discussion here.

I should like to add emphasis to one condition that, it seems to me, the textbooks on otology do not sufficiently stress, that is, the qualitative failure of sounds to register in the higher cerebral centres. There is a full registration of sound volume, but the qualitative analysis necessary to translate these sounds into spoken words is absent. The selective apparatus in the cochlea or hearing centres in the cerebrum do not register properly, and the noise is not appreciated as a spoken word. These patients with progressive deafness will nearly always tell you that they hear your voice, but that they do not know what you are saying. Another way in which this failure of sound registration manifests itself is in the very early stages of a case of progressive systemic deafness. At from three to five feet distant the patient will begin to miscall a greater or less number of the words spoken to him, and at the full distance of twenty feet he is repeating the same number of words correctly. His sound registering apparatus is interfered with, rather than his noise perception apparatus. In life this patient hears part and guesses part, and is credited with inattention. This failure of registration is not true of individuals with average hearing. At the end of their hearing distance for a whispered voice they simply cease hearing a sound. As long as they hear a sound, it registers as a definite word or noise or musical note. The sound registering faculty is in full working order.

Some of these patients show an extreme relaxation of the drum membrane, particularly in its larger, posterior segment. When examined with the pneumatic otoscope the excursions are extreme and the drum appears thin, dry and atrophic. It is so relaxed that it does not seem possible for it to be

regenerated into a tense, vibrating structure. This condition of the drum membrane is not important from a diagnostic viewpoint, as the diagnosis must be made from a functional examination of the ear and a physical examination of the patient. It has, however, extreme importance from the viewpoint of prognosis, as will be pointed out later.

The three periods of life at which progressive deafness most commonly has its onset, are at the crises of life—puberty, adolescence and the menopause, and to this may be added a fourth critical period, the oncoming of actual old age. The severest cases of progressive systemic deafness, the group that supplies the largest number of cases of so-called otosclerosis in later life, are those having their inception at puberty and adolescence in girls. These are the most trying times in their lives, the times of the greatest physical and mental stress, and their ears suffer. In this connection, it must be remembered that the male goes through the same physiological crises as the female, but as the crisis is less marked, so the ears suffer less. In connection with the onset of deafness at puberty and adolescence, it is to be remembered that ossification is still incomplete, and the result of loss of control of phosphorus and calcium is more destructive and lasting in its results than at a later time in life, when the ossifications are complete. Closely allied with the sexual crises of life as a cause of the onset of deafness is the effect of pregnancy. Many women will state that their deafness had its onset or was made worse during the progress of pregnancy.

Next in importance as a cause of the onset of progressive systemic deafness, after the crises of life, is to be put down to worry and shock. This worry may be over finances, over one's own health or the health of near friends, or any of the numerous things humanity is given to worrying over. It may owe its inception to a sudden shock or fright. I have one patient, a woman over sixty years of age, who has been through a trying personal illness, and whose husband has had one stroke of apoplexy. She was making excellent progress when the husband suffered a second stroke and for a time his life was despaired of. About the time that the husband seemed to be out of immediate danger, a sister seventy years old came to visit her and was taken down with neuritis and had to be cared for. Under this strain of worry and fatigue, my patient's hearing receded very markedly, and it is difficult at this time to hold the gain so far secured.

The onset of progressive deafness may also follow a severe illness. This is more likely to be the result of a toxic condition, such as influenza, or a long continued chronic illness of an exhaustive nature. On the other hand, the onset may be insidious and without discoverable cause. Patients will come with the first complaint that they are unable to hear the telephone with one or the other ear, and examination will show an advanced state of deafness in that ear, and perhaps a beginning involvement of the other ear, or the patient's friends may be the first to complain of the onset of deafness. Sometimes these patients cannot fix within considerable limits the time within which

they began to be bothered with head noises and deafness, although they fix the onset of tinnitus with much more definiteness than they do the onset of the progressive deafness. It does not seem to be established that there is any connection between mild inflammatory conditions in the ear and the progressive deafness. The two conditions are more likely to be coincident than to bear a causal relationship one to the other. One condition is purely inflammatory, the other infiltrative and degenerative in nature.

In the present state of our knowledge, it is not possible to say with certainty which of the glands of internal secretion are involved in progressive systemic deafness. Yet from the known pathology and symptomatology, it is possible to mention some of the glands that are responsible for this syndrome. These include, first, that group of glands involved in the control of calcium and phosphorus metabolism, that is, in the control of bony metabolism; second, there are involved the group of glands concerned in the control of oxidation in the body. These two groups really can be combined into one great group which controls bodily metabolism.

The first and most important of these is the thyroid gland. This gland of internal secretion has a definite control over the oxidations and metabolic activities of every cell in the body. It also exercises a special control over calcium and phosphorus metabolism. But, combined with it in this control of the cellular metabolic activities of the body are the interstitial cells of the sex glands. That the internal secretion of the interstitial cells of the sex glands influences bony metabolism is amply evidenced by the differences in the bones of castrated and noncastrated animals. This control of the interstitial cells of the sex glands over bony metabolism may be limited to the shape of the bones, or it may be extended to the metabolism of calcium and phosphorus directly. In the gross, this change is limited to the fact that the bones of the castrated animals are longer and more slender. The castrated animal also suffers a fatty degeneration of his other tissues, particularly the muscular. As a consequence, the muscular and connective tissues suffer from a lack of tone. That castration produces a profound change in the bodily metabolism of an animal is amply evidenced by the difference in the edibility of the flesh of the two animals. That this change in metabolism extends to the nervous tissues, witness the psychic difference.

In those patients who suffer from a lack of vascular tone and fatigability, there is also a probable involvement of the suprarenal gland, as it is a part of the function of the suprarenals to watch over vascular tone and relieve fatigue. It is also probable that the suprarenals join with the interstitial cells of the sex glands in keeping up the tone of other tissues of the body, as witness the extreme asthenia in cases of adrenal involvement, of which Addison's disease is the best known example. In some cases the pituitary gland seems to have some influence on bony metabolism in a way which is not easy to explain, and in regard to which there is a wide difference of opinion.

In any discussion of the glands involved in these

cases of progressive systemic deafness, it seems worth while to call attention to a condition that is sometimes met in connection with this disturbance. I refer to the condition of postmenopausal or functional high blood pressure, which follows the loss of a part or all of the internal secretion of the ovary at the time of the menopause.

In the control of calcium and phosphorus metabolism in the body, the parathyroid and thymus glands are both said to play a part. This, however, is not well enough understood at the present time to justify any positive statements as to their use in the condition under discussion. When the physiology of these two glands is better understood, they may come to play a part in the therapeutics of progressive systemic deafness. It seems desirable, in the discussion at the present time, to stick to facts that seem to be well established.

THE ROLE OF HEREDITY.

It has been quite well established that what is commonly called heredity plays a part in the etiology of progressive deafness. In any discussion of heredity, it becomes necessary to distinguish between true heredity and the intrauterine acquirement of subnormal conditions. In view of the strong tendency for the offspring to be an anatomical copy of the parent, it seems entirely possible for a tendency toward a weakened or subnormal glandular system to be transmitted by true inheritance, and this undoubtedly does occur. However, the great mass of so-called inheritance must be credited to intrauterine acquirement. A woman with a thyroid gland just sufficient or not quite sufficient for her needs becomes pregnant. The pregnancy immediately throws an added burden on her thyroid gland and causes its hypertrophy. As the intrauterine development of the child progresses, she must not only supply thyroid gland substance for herself, but also for the child. If there is less thyroid substance than is required for the development of the child along proper lines, then its thyroid will be subnormal, and later in life will fail to function properly, and will not stimulate the other glands, particularly the sex glands, to a proper development. As a consequence that individual must go through life subnormal in so far as his glands of internal secretion are concerned.

Breast fed babies receive the necessary amount of thyroid substance through the mother's milk, and this in turn stimulates the thyroid gland to a proper development. Bottle fed babies, on the other hand, do not get an adequate supply of thyroid secretion in cow's milk, and this lack may not only prevent proper bodily development but may also lead to a thyroid gland that is inadequate to the needs of the body.

PATHOLOGY OF PROGRESSIVE SYSTEMIC DEAFNESS.

Keeping in mind the pathology of minor thyroid deficiency and also the pathology of sex gland loss, we are now in a position to reconcile the pathology and symptoms of the local ear condition, and to state the pathology in the light of the etiology and symptoms. As I have previously pointed out (1) the pathology of minor thyroid dyscrasia is essentially that of the so-called cellular infiltration. The

older, worn out cells of the tissues are not destroyed, and the new cells are not adequately formed. This leaves an excessive number of cells, with crowding, in the tissues, and the condition is spoken of as infiltration, although this is not a good term. Sub-oxidation would more correctly describe the condition present. With this infiltration, there is a condition of myxedematous degeneration, which is mild or grave in direct proportion to the disturbance of function of the thyroid gland. As I have already said, the pathology of gonadal or sex gland deficiency is that of a mild fatty degeneration, with bone changes that are undoubted but not so well understood. An extreme example of the bony change of sex cell origin is the osteomalacia occurring in poorly nourished women after repeated pregnancies.

Now combining this into a coherent picture, we have that of infiltration and cell crowding, with mild myxedematous and fatty degeneration. As a result of this cell crowding and degeneration, there is poor local circulation and further depression of metabolism. With this, because of the faulty action of the two glands, there are changes in the phosphorus and calcium metabolism. In addition, there is increased cellularity in the vascular and Haversian spaces of the bone. Later, in the stage of atrophy, there may be absorption and contraction of the cellular elements, and a condition of osteoporosis supervenes.

Now to apply this pathology to the local condition under discussion. It is possible that in those cases of thyroid and sex gland insufficiency that give ear symptoms, the bone changes already described are more marked in the temporal bone than generally throughout the body, because of some local predisposing factor. The first change is that of infiltration and thickening in the drum membrane and throughout the middle ear and its connections. At a later time, there will be a stage of atrophy. As a result, the connective tissues of the middle ear, including that of the drum, will be of low tone and so will lack vibrating tension. The muscles will lack tone, and these should, under careful examination, show some evidence of fatty infiltration, as should also the ligaments of the ossicles. The connective tissues of the labyrinth and cochlea are also of low tone and lack resilience, and this will, in part, account for the failure of sounds to register that has already been spoken of under symptomatology.

It is, however, in the nervous element of hearing that the most profound results of the infiltration and degeneration are shown. The nervous tissues are the most delicate in their adjustments. They do the most work, as judged by oxidations, use up the most energy, have the least reserve store of oxidizable material, and suffer the most profound effects from slight causes of any tissue in the body. The nervous structures suffer the same infiltration and fatty degeneration that is present in other tissues of the body. This extends from the end organ in the cochlea, through the cochlear branch of the eighth nerve, and on into the perception and interpretation apparatus in the cerebrum. The threshold stimulus is dulled all along the pathway. The end organs in the cochlea are less responsive, the transmission is less free, and the registration in the cerebrum is interfered with. Those cases showing the

late effects on the nervous apparatus are classed as nerve deafness, while at an advanced stage, when the atrophic end results are present in the middle ear and temporal bone and the cochlea, come to be called otosclerosis, particularly if the course has been a stormy one.

TREATMENT OF PROGRESSIVE SYSTEMIC DEAFNESS.

The inflation of these patients is to be wholly condemned. The drum membrane, the ligaments of the ossicles and the middle ear muscles are already below normal as to their tone and beginning to relax, and inflation detracts from the tone they have left. These structures are not accustomed to carrying a load of tension, as there is, under normal conditions, no appreciable condensation of the air in the middle ear. Even in proper blowing of the nose the pressure within the middle ear is not increased, the Eustachian tubes remaining closed. Tissues that will lose tone and relax practically under their own weight are certainly not prepared to resist and will not resist the traumatism of a vigorous inflation.

Infected adenoids and tonsils must be removed and abscessed and decaying teeth must be cared for as a part of the treatment. These infections all throw an increased load of detoxication on the glands of internal secretion and render their action less efficient. In instituting endocrine treatment of progressive systemic deafness the glands concerned must be freed from as great a load of detoxication as may be, and in so far as possible, permitted to function normally. In pursuing this object, all local infections must be removed. To secure the best results, however, from the administration of endocrines the treatment must be instituted at the earliest possible moment. There will come a time when the degenerative changes have reached such a stage that restoration of function is not possible, and when there may be an organic destruction of nerve endings in the cochlea, or an atrophic degeneration of the organ of Corti, and similar conditions.

I should like to preface the discussion of the endocrine treatment of progressive systemic deafness with the statement and caution that no one should make a serious attempt at endocrine treatment unless he has made a study of the principles of treatment and physiology from the viewpoint of the glands of internal secretion. The administration of endocrines is not entirely without danger, and should not be undertaken lightly. There is no routine treatment, and simply because I have secured good results in a given case from a certain capsule is no justification for the routine use of that capsule. There is and must be an individualization in each patient treated. For now, more than ever, we are treating a patient and not a case.

With these reservations, I may be permitted to state that I have treated many of my patients with an adrenospermin compound. These are the so-called thyroid type of patients. If the patient presents both pituitary and thyroid symptoms, then I am accustomed to begin with a mixed gland substance. It is to be remembered that it is necessary to prescribe stock formulas in endocrine treatment. The gland substance must be at once made up into a capsule or tablet that will protect it

from oxidation, and prevent deterioration. For this reason, it is not possible to write prescriptions for the druggist to prepare. With functional high blood pressure, as in postmenopausal conditions, the situation to be met becomes complicated. Here we have an overactivity of the adrenals with a depression of the sex gland function. The result is that the adrenals lack control. For the relief of the high blood pressure a number of endocrines have proved useful, and among these, sex gland substance is of the most importance in the present discussion. Pancreas substance is a direct antagonist of the adrenals, and so is efficient in some of these cases in reducing blood pressure. Bandler recommends placental substance very highly for the reduction of postmenopausal high blood pressure. In a similar way other conditions must be met as they arise. The blood pressure seems to be the key to the control of the treatment. If the pressure is low, adrenal substance is to be included in the treatment. If the pressure is normal or high, then the treatment will consist of a combination of thyroid and sex gland substance, the proportion of sex gland being increased as the blood pressure increases. The doses must be kept small, as the administration will of necessity extend over a long time. The initial dose of thyroid substance should not be more than one eighth of a grain, usually less.

As to the permanency of the improvement, it will require many years to arrive at a final conclusion on this point. It will very naturally suggest itself that the permanency of the improvement will of necessity depend on the amount of suppression of the physiological activity of the glands affected. If, in the individual, there was a normally acting set of

endocrine glands present, and their secretions have been reduced by a severe fright or shock or, toxic illness, then the gland or glands involved may be restored to normal and the treatment discontinued. On the other hand, if there is a permanent subnormal condition of the patient's endocrine system, and this cannot be brought up to the point where it will meet the requirements of the patient's bodily activity, then that patient will, of necessity, have to be under more or less continuous treatment. He will, however, learn to judge of his condition more accurately than any physician could judge of it and will be able to take his necessary minimum of endocrine substance, subject to some guidance from the physician.

In these patients, where the administration of endocrines is likely to continue for a considerable time, their administration must not be continuous. This must be intermittent for a week or ten days in each month, and in women this period should begin a few days before menstruation sets in and continue for a few days after it has ceased. Occasionally, in those patients in whom the preservation of the hearing necessitates the continued administration of endocrine substance, there should be intermissions extending over one or two months, or even for longer periods, if the gland deficiency present will permit it.¹

The Effect of Pituitary Extract on the Rate of Urine Formation in Man

By R. McBRAYER, A.B., M.D.,
Sanatorium, N. C.,

Clinician and Director of Laboratories, North Carolina Sanatorium for the Treatment of Tuberculosis.

It was at the suggestion of my former professor, Dr. A. N. Richards, who holds the chair of pharmacology and pharmacodynamics in the Medical School of the University of Pennsylvania, that this study was undertaken. The infectious enthusiasm, kind encouragement and stimulating influence of Dr. William deB. MacNider, professor of pharmacology, University of North Carolina Medical School, have also aided me valuably during this investigation. Therefore, to these two men, as well as to my father, Dr. L. B. McBrayer, who ably and tirelessly assisted me in the actual work, I am deeply indebted.

Before taking up the actual work of which this paper is the subject, let us briefly review the current teaching of the pharmacology of pituitary extract. Here we may state that the preparation used in this study is the obstetrical pituitrin made by a reliable drug house, which, in a recent personal communication, states that this product is a quantitatively

standardized aqueous extract of the infundibular portion of the pituitary gland, and that obstetrical pituitrin is just one half as concentrated as surgical pituitrin. This product was used because we believe with Rowntree (1) that for such studies it is probably the best preparation available.

The manufacturers' statements concerning the pharmacological action of this preparation agree with the statement in that admitted authority (2) which says that "when the extract is injected intravenously, the blood pressure rises"; that this "rise in pressure is due to the constriction of the peripheral arterioles, as is shown by the lessened volume of the organs." He concludes that "the pituitary substance must act directly on the muscle fibre," because this action is not interfered with by severing the vasoconstrictor nerves or by paralyzing the myoneural junctions with ergotoxin. However, this constrictor action on the arterioles seems not to be

without exception, for the same writer finds that "one of the earliest observations was that pituitary extract injection was followed by a profuse secretion of urine, generally accompanied by dilatation of the renal vessels and an increase in the volume of the kidney," although there is some conflicting evidence to prove that this is the complete *modus operandi* in the diuresis. Cushny's statements are arrived at by reasoning from analogy, in that they are mainly based on animal experimentation. Norris states practically the same thing: "It (pituitary extract) also has a diuretic effect due to direct stimulation of the renal cells, usually aided probably by a concomitant vasodilatation, because there is no constant relation between pituitrin diuresis and either systolic or pulse pressure or the ratio between them."

Realizing that a textbook can hardly be out of the hands of the printer before subsequent studies have antiquated parts of it, we communicated with fifteen

unpublished experiments, that "the rise in systemic blood pressure which follows the use of pituitary extract and the associated vasodilatation of the renal vessels is not the essential elements in pituitary diuresis. The rise in systemic pressure and the renal vasodilatation favor diuresis from pituitary extract, but if the renal epithelium is injured by an anesthetic or by uranium nitrate no diuretic effect is obtained from pituitary extract, even though the general and local circulation is favorably influenced for diuresis. The primary and essential element in pituitary diuresis is its ability to stimulate renal epithelium."

Certainly you will agree that the current and generalized teaching on this subject is that pituitary extract is a diuretic for man, although in 1915 Korschegg and Schucter (4) reported that, in normal persons, the volume output of fluid and solids could be lessened for sixteen hours by the subcu-

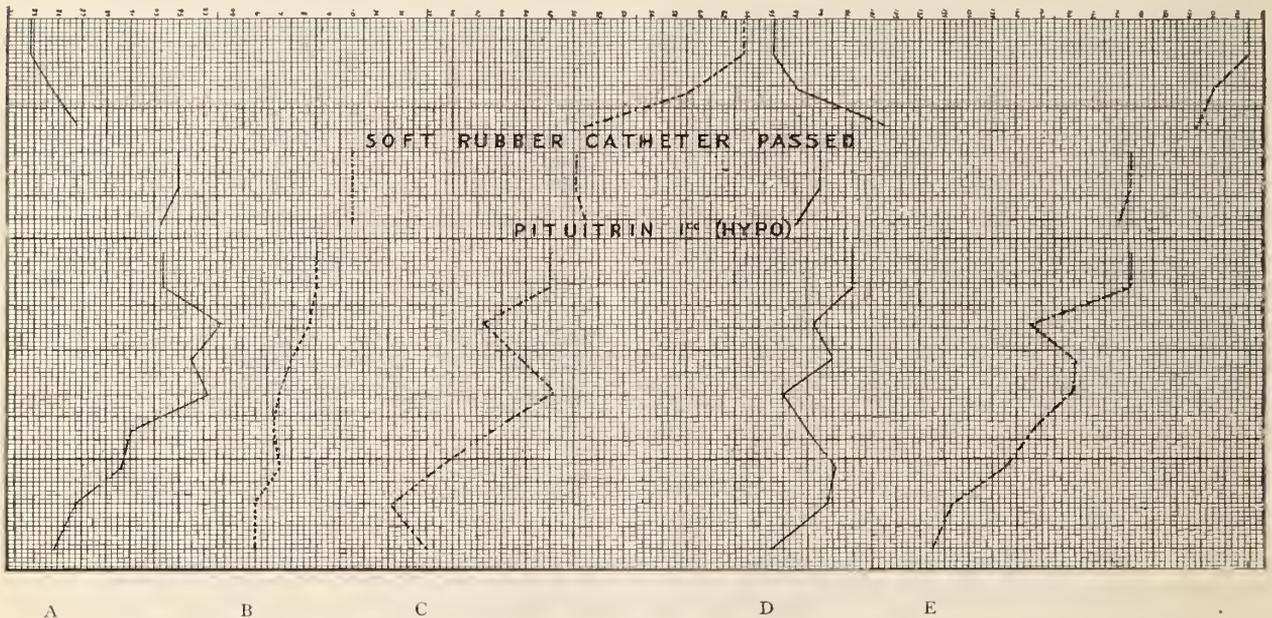

FIG. 1.—North Carolina Sanatorium weight chart. A, shows pulse rate; B, urine flow; C, pulse pressure; D, diastolic blood pressure; E, systolic blood pressure.

of the best medical schools in the United States, requesting the professors of pharmacology to give us their current teaching on the pharmacological action of pituitary extract with reference to urine formation. To date, Columbia University, Johns Hopkins, University of Michigan, University of Virginia, Washington University, Yale University, Cornell University, University of Chicago, Tulane University, University of North Carolina and the University of Pennsylvania have replied.

To crystallize their replies, they would be as follows:

The subject is yet too undeveloped to permit of dogmatic teaching; however, we superficially mention its diuretic effect, using Cushny's textbook as the basis for this teaching, or, as a few did, entirely avoid answering the question.

MacNider, referred to above, than whom there is no greater authority on the kidney, considers, in a personal communication to us based on

taneous injection of one to two c. c. of pituitary extract.

TECHNIC OF EXPERIMENT.

Our study was undertaken in the following manner: The seven subjects used were patients in the North Carolina Sanatorium, undergoing treatment for active pulmonary tuberculosis. In a warm room, free from noise, interruptions and drafts, each of the seven ambulatory males was singly placed at complete and comfortable rest in a semi-sitting posture on a standard recliner. His position and clothes were adjusted for subsequent catheterization to the point that this operation did not require a single movement on his part. After the subject had rested for fifteen minutes, the five and one half inch cuff of the Faught mercury sphygmomanometer was applied to his right arm, and the systolic and diastolic blood pressure and the pulse rate (counted in half minutes) were recorded at regular intervals—usually two minutes—until it appeared that each

had reached a constant level or rate. This required about twenty-five minutes. The subject was now catheterized with a soft, medium sized rubber catheter. This was done with the minimum of confusion, noise and movement on the operator's part, and with the least possible discomfort to the patient. When the bladder had been emptied and a constant dropping of urine from the catheter had been established, the amount of urine flow per unit of time (usually two minutes) was measured. This, in our opinion, was taking the urine from the bladder at the rate at which it flowed into the bladder from the kidneys. Along with this measured urine flow, the systolic and diastolic blood pressure, and the pulse rate were taken and recorded as detailed above. The four readings were regularly continued until each became practically constant, which required about thirty-five minutes. One cubic centimetre of pituitrin was now given subcutaneously in the left deltoid region. This was done with the least possible disturbance to the patient, blood pressure cuff and catheter. Immediately the readings of the systolic and diastolic blood pressure, the pulse rate and amount of urine flow per unit of time were regularly continued and recorded. This procedure was usually continued for an hour after the administration of pituitrin.

Now let us take up the results obtained in each case.

Note: The total solid estimations referred to below were obtained by that old and often proved rule (5) which has us multiply the last two figures of the specific gravity by two, the product being the total solid output in milligrams per thousand c. c. of said urine. We realize that this method is not truly scientific and accurate; nevertheless, it was the only available method possible.

CASE 2003.—E. B. S., aged twenty-six years. Classification: far advanced, B. No. 3. Three urinalyses showed: tubercle bacilli, white blood cells (mainly small lymphocytes), pus cells (few). Phenolsulphonephthalein output: two hours, 65 per cent.; three hours, 72 per cent. His urine output was studied, as above outlined, for an hour and eighteen minutes, with the following results: The rate of urine flow averaged 1.25 c. c. per minute for the fourteen minutes just preceding the administration of pituitary extract. During the first thirty-two minutes immediately following the extract, it flowed at the rate of 0.992 c. c. per minute, which was a twenty-one per cent. decrease in output per minute. During the next thirty-two minutes it flowed at the rate of 0.8 c. c. per minute, which is a thirty-six per cent. decrease. The output of solids during the fourteen minutes before the drug was at the rate of 0.05 mg. per minute; while, during the first thirty-two minutes following the drug, the solid output was 0.0396 mg., or a decrease of twenty and eight tenths per cent. per minute. The output of solids for the second thirty-two minutes was at the rate of 0.032 mg. per minute, or a decrease of drug was 1.020, as was the specimen following the drug.

CASE 1852.—J. W. W., aged twenty-nine years. Classification: incipient, A No. 1. Urinalysis, based on two examinations, showed a trace of albu-

min, occasional hyaline and granular casts, specific gravity 1.034. Phenolsulphonephthalein output: two hours, 45 per cent.; three hours, 55 per cent. Urine output studied as above for one hour and twenty-one minutes. Average rate of urine flow, during the twenty minutes preceding drug, was 2.3125 c. c. per minute; during the first thirty-one minutes following the drug it was 0.9322+ c. c. per minute, or a decrease of sixty per cent. During the next thirty minutes the rate of flow was 0.7066 c. c. per minute, or a decrease of sixty per cent. No estimation of solids or specific gravity readings were done in this case.

CASE 1840.—W. S. M., aged thirty-two. Classification: incipient, A No. 1. Two urinalyses showed: Albumin plus; occasional white blood cells. Phenolsulphonephthalein output: two hours, 41 per cent.; three hours, 55 per cent. Urine flow was studied, as above, for one hour and forty-seven and five tenths minutes. During thirty-one minutes prior to drug, average rate of flow was 0.9677+ c. c. per minute. During first thirty-six and five tenths minutes following administration of drug, the average rate was 0.8219+ c. c. per minute, or a decrease of seventeen per cent. per minute. During the next forty minutes, the average rate of flow was 0.75 c. c. per minute, or a decrease of twenty-three per cent. No estimation of solids or specific gravity readings were made.

Realizing that this series of studies is numerically small; knowing, however, that the facts were obtained in a very detailed and accurate manner, and furthermore appreciating the utmost consistency in the results, we feel that the following conclusions are warranted:

1. During the first hour following the hypodermic injection of medicinal doses of pituitary extract, the urine output is markedly decreased.
2. During the same period of time the total output of urinary solids is markedly decreased, both relatively and actually.
3. During the same period of time there is a marked and constant decrease in the systolic, diastolic and pulse pressures, and pulse rate, which decreases appear definitely related to the decrease in the fluid and solid output of the urine.

Realizing that this decrease in the output of urine and urinary solids might be only a temporary affair, we undertook the study of these two problems in fractional twenty-four hour specimens. We regret to state that our series of cases is yet too small and the data obtained too inconsistent to permit of any conclusions.¹

Editorial Articles

PRACTICAL ENDOCRINOLOGY

Some of our less progressive coworkers seem concerned lest we desert the old standbys of medicine and get lost chasing a will o' the wisp—endocrinology. This warning would have its value if things were as they say they are instead of being as they are. If the modern endocrinologist worked with test tubes; if he neglected to consider his patient as an integrated organism; if he asserted that endocrinology was an open sesame to the cure of all diseases and deformities, the warning would be justified. But for the present we are little concerned about the omens predicted. Endocrinology is making rapid strides, not so much from a therapeutic point of view but from the viewpoint of a better understanding of the organism as a whole, of its powers of coordination, of its wonderful powers of direct and indirect compensations, these compensations being most clearly shown in the endocrine chain. No more stimulating field of medical endeavor has been encountered in a long while. The importance of extensive and minute history taking has been emphasized, as has the importance of various markings. Every specialty has been affected. Every branch of medicine and surgery has been influenced by the discoveries of endocrinology. This is not a new subject. Endocrine products have been used empirically for centuries.

The editors of the *NEW YORK MEDICAL JOURNAL* have long since realized the importance of practical endocrinology. For some time past we have collected papers from the most progressive workers in this field, in America and abroad, and have offered them to our readers in the form of special numbers. The present issue of the *JOURNAL* is one of the best we have managed to create. We shall not emphasize the standing of the various workers or the importance of the papers. We can only state that the papers have been selected with great care. Much material is presented that is absolutely new. We feel that every paper is worthy of careful reading by every medical man, no matter what his specialty may be. This cannot be said of an equal number of papers in any other medical journal. Numbers such as this are of more value than an ordinary textbook, a textbook which would cost as much as a year's subscription to this journal. We feel that we are rendering a distinct service to the medical profession in issuing our various special numbers, the most important of these being the endocrinological numbers.

SACROILIAC DISEASE

So many common symptoms, lately classed under a few indefinite titles, have been found to centre causally about an abnormal condition of the sacroiliac joint, that sacroiliac disease, as it has come to be called, seems a new and increasingly frequent affection. The very indefiniteness of the words lumbago and sciatica or crick in the back, tell of the vagueness of pathological knowledge of their cause, but none of these conditions is new and they are probably not much more frequent since they have been traced to their local setting.

That sacroiliac disturbances are not more frequent is to be wondered at when the joint is studied, for probably no structure in the body seems more unfitted for the stress and strain that is thrown upon it. The sacrum is wedged between the ilia with surfaces for articulation well nigh vertical and of only one by three or four inches in size. The ligaments are not heavy and the musculature seems of small moment. For an animal built on the horizontal plane it might be called perfect, for certainly there was no downward pressure upon the wedge, but, when the upright posture was assumed, a weight equal to that of the head, arms and practically all of the trunk—say of a hundred pounds in the average adult—was thrown upon the wedge. When our ambitious ancestors began to throw stones and to wield clubs, the weight of the stone, club, and later of hod, wheelbarrow, bed mattress or what not might suddenly be added to the body weight, while, in the obese, the burden might easily be added to by another hundred pounds.

How marvellously adaptive the joint has been and still is, is shown by the infrequency of symptoms referable to this joint in young people and in those who make a reasonably varied use of it. It is the unusual use or use in the unusual position which finds this structure napping: the school teacher or store clerk attempting to lift a barrow of dirt, or the middleaged gentleman of leisure who throws a stone too violently at neighbor's trespassing chickens, or the woman who has long given the joint the artificial support of a corset and who is taken with a crick in the back as she is getting out of bed. Whether this latter incident ever occurs in those who go uncorseted has probably not been studied but we doubt if it does.

That sacroiliac trouble is especially likely to occur or recur at the menstrual period, leads us to surmise that there is yet much to be learned about the be-

havior of joints. Do ligaments lengthen, does the cartilage become thinner at times, or is the muscular support of this particular joint more important than seems possible?

That the joint is subject to injury of a lasting nature is revealed in the dissecting room, partial or complete ankylosis being found, as well as less significant signs of trouble. A good deal of chronic lame back is doubtless a result of chronic arthritis, the metabolic disturbances following repeated local injury.

Among repeated injuries of a minor kind which must have their effect, the striking of hard heels upon hard pavements must be considered not unimportant, for the sacroiliac joint bears the brunt of the jar. Rubber heels would certainly have some effect as a prophylactic. Correction of faulty feeding must be of benefit to this as to all other joints, while an active use of the joint in a variety of movements is also of general as well as local benefit.

HYDROMINERAL AND CLIMATIC TREATMENT OF RHEUMATISM AND HEPATIC DISEASES

During the past thirty years a great movement has been set on foot, both in Europe and in this country, in favor of utilization of the hydromineral and climatic treatment of chronic affections. It is generally admitted that this method represents one of the most powerful agents in combating affections that are difficult to cure. The nature of the treatment in detail is naturally in the hands of the physicians at the various resorts who have specialized in the matter. The general practitioner cannot be expected to be familiar with the particular properties of the different springs, any more than with the method of applying the balnear and physiotherapeutic measures employed at each resort. However competent a physician may be from the point of view of hydrology he nevertheless hesitates to give advice regarding the choice of a spring or methods of application. Detailed instructions should not be given to any patient as to what he ought to do at any other resort, because he should make it a question of principle to leave this matter to be decided by the local man whose experience has been acquired at the resort. It takes the latter many years of close observation to familiarize himself with the action of different mineral waters, both when imbibed and when used externally.

Naturally at this season of the year physicians are casting about for places to send their patients. If possible they should personally inspect a resort before referring patients, not to be caught by an antique

bathing establishment, with no modern improvements nor efficient service, where a new doctor is hired each year, usually splitting his fee with the bath-house company and obtaining his consultation principally from professional steers who frequent the hotels and parks of the resort with no knowledge whatever of the right prescribing of the waters. The local physicians must stand and take this condition of affairs, and it is no wonder that the physicians who send their patients to such a combination are disappointed in the results when they return.

Then there is another consideration that requires special attention. It is not enough to select a health resort in accordance with the therapeutical indications, we must also as far as possible take into account the economic conditions of the resort. Certain watering places have been organized in view of a rich clientele, while others are accustomed to receive patients of moderate means, although there are some, it is true, provided with hotels of every sort, where the graft is as strong in some instances as the mineral waters supplied. It would therefore be a tactical error to send a wealthy patient to a resort ill provided with the comforts of life, just as it would be to send persons of moderate means to a place where there are only first class hotels. In any event, it would be well for the physician to ascertain conditions carefully before he refers his patients whom he naturally expects to come home improved.

PHYSICIAN AUTHORS: SIR THOMAS BROWNE.

There are few physicians in the seventeenth century who took the pains to acquire as thorough a scientific knowledge of his profession as did Sir Thomas Browne, the famous author of *Religio Medici*. Although he was content to be merely a country physician—with antiquarianism and literature as his hobbies—Sir Thomas was one of the best equipped practitioners of his day.

He was born on October 19, 1605, near London, and after having attended Winchester College and Broadgate Hall (now Pembroke College), he began his medical studies at Oxford University. But the medical course offered at Oxford in those days was exceedingly incomplete. It consisted solely of a little perfunctory reading of Hippocrates and Galen in the original, and even the study of the drugs and plants was of a sketchy character. There was no hospital in connection with the university, and therefore no clinical school. "If Browne went through the poverty stricken classes of Oxford medical teaching," says Edmund Gosse, "it could only have been to assure himself of their worthlessness. His

writings may be searched in vain for the slightest sign of loyalty to Oxford or gratitude for anything she taught him." And so, dissatisfied with the meagre education in medicine offered at Oxford, Browne went to the continent and spent a year at each of the three most famous schools of that day. The first of these was Montpellier—where Rabelais got his medical degrees—where the basal training in the profession was said to be more thorough than anywhere else in the world. Montpellier was the first school to give public demonstrations in anatomy and nowhere else was the new science of botany so thoroughly taught. As an indication of how far the medical science has progressed since that time, it may be mentioned that when Browne was a student at Montpellier the school taught that the life distributed throughout the body was due to an organic soul, the vital principle of which animated the tissues and gave warmth and movement to the body. This was the theory of vitalism which Descartes rejected. The university, after a bitter fight, also rejected the theory a short while later.

After finishing at Montpellier, Browne went on to the University of Padua, then regarded as the centre of the world of science. "It was in Padua," says Gosse, "that for upwards of a century young men from all parts of Europe had received surgical teaching such as could nowhere else be supplied. The school was preeminent in all branches of surgical and anatomical science."

From the University of Padua Browne went to the comparatively new University of Leyden, which had lately developed educational facilities that made it of great importance to students of medicine. Leyden laid emphasis upon the study and development of chemistry, whereas Montpellier and Padua stressed anatomy and surgery. Before Browne left Leyden he received his degree of M. D. and shortly thereafter, probably in the fall of 1633, he returned to England. "Thus he examined all that the fermenting scientific world of France, Italy and Flanders had to offer of what was curious and new," says Gosse. . . . "He was able, without painful effort, to throw off, or to keep from acquiring, the mental prejudices which were typical of the strenuous, straitened English tradition of the early seventeenth century." All of which, to a large extent, accounts for *Religio Medici*.

Upon his return to England Browne settled at Shipden Hall, near Halifax, and began practising, but in 1637 friends induced him to move to the much larger town of Norwich, where, as Charles Whibley tells us, "he spent more than forty years in the tranquil practise of medicine, in the study of antiquities, and in the pursuit of humane letters."

In the year that he went to Norwich he was enrolled as a physician at Oxford and two years earlier he had taken a degree at the London College of Physicians. At Norwich he not only was "much resorted to for his skill in physic" but his home, a "paradise of rarities," became the Mecca of English antiquaries. He took a keen interest in anything and everything of antiquarian nature—urns, coins, bones, eggs, fossils—and was considered an authority on such things, but his writings show him to have been extremely fallible along that line. It is purely for their style that these writings are of any interest today.

Although *Religio Medici* was written before he went to Norwich, and before he was thirty years old, it was not published by its author until 1842, after a highly inaccurate copy of it had fallen into the hands of a piratical publisher. It has survived almost alone among the treatises of the seventeenth century, says Whibley, "because it is set to perfect music, for Sir Thomas Browne was a musician who played upon the instrument of speech with the skill of a conscious artist." Bulwer-Lytton called it "one of the most beautiful prose poems in the language" and Prof. George Saintsbury said that "as an artist, or rather as an architect of words in the composite and florid style, it is vain to look anywhere for his superior." Coleridge called Browne "a writer of great genius" and many other eminent critics have been lavish in their praise. Browne was a disciple of Montaigne, and he, in turn, has had a great influence on later writers, notably Charles Lamb. *Religio Medici* is a treatise on "the religion of a physician." Gosse calls it "a defense of the attitude of a mind that is scientific and yet reverent. The subject of the treatise is religion as it appears . . . to an intellect which for a long time past has been concerned exclusively with natural experiment, and which comes back to religion habituated to the experimental attitude."

Browne's other writings included *Pseudoxia Epidemica*, or *Vulgar Errors*, published in 1646; his volume on *Hydrotaphia*, or *Urn Burial*, published in 1658; *The Garden of Cyrus* and some other works published under the titles of *Certain Miscellany Tracts* in 1684, *Christian Morals* in 1716, and some other writings which were first published in his *Works*, which appeared in 1686, four years after his death.

During the Civil Wars Browne sided with the Royalists and in recognition of this fact he was knighted during a state visit of Charles II to Norwich on September 28, 1671. He died on October 19, 1682, the day on which he completed his seventy-seventh year.

REFORMER OR REALIST.

It is extremely unfortunate that the medical aspects of the venereal diseases and their prophylaxis always have been more or less linked up with and frequently obscured by the moral considerations involved in the subject of prostitution as a social evil. Prostitution always has been regarded the handmaiden of vice and immorality, and therefore legitimately within the purview of moralists, theologians and other types of nonmedical social workers. On the other hand, the venereal diseases, which are to a very large degree the sequelæ of prostitution, are essentially medical in character, and naturally come within the province of the physician. Hence the inevitable conflict of views.

The moralist aims to suppress public prostitution, and believes that this desirable end having been attained, venereal disease and its associated ills would immediately disappear from the face of the earth. As a result, he hails with delight the cleaning up of a redlight district, or the disappearance of the unfortunate soliciting woman from the city's pavements, and when these ends are accomplished he feels that his work has been well done. It is obvious to everyone else, however, that his success lies solely in the suppression of the outward manifestations of the evil, for it is undeniably impossible to control or even influence the practice of hidden or covered prostitution that does not show itself in some form or other. The physician, on the other hand, especially he who sees much of the venereal diseases in his daily practice, is not seriously impressed by these activities. He knows there is little or no perceptible decrease in the amount of venereal disease he is called upon to treat, even after his city or town has been cleaned up and the professional prostitutes have been driven out of the town.

It is not to be wondered at; therefore, that he views the subject of prostitution and its suppression in a light that does not bring joy to the ardent social hygienist, even though he be a strong believer in the evils that go with society's greatest ill. This is made evident by an article which appeared in the *NEW YORK MEDICAL JOURNAL* and an editorial critique on the same which appeared in the *Social Hygiene Bulletin*, June, 1921.

Dr. Abr. L. Wolbarst, of New York, the author of this article, declares that public prostitution in New York City "has been so severely dealt with that it cannot any longer be considered a serious factor in the social life of the community"; but he maintains that while the outward form of prostitution has changed, the substance remains unchanged; that "its manifestations may be suppressed in one direction only to reappear elsewhere

in another form." He ends his article with these conclusions: "I desire to emphasize the belief that the suppression of prostitution has not diminished illicit sexual relations; that it has resulted in widespread moral looseness and sex stimulation; that it has caused the moral and physical ruin of many girls who might otherwise have remained clean and unscathed; and finally, that it has not perceptibly diminished the amount of venereal disease, but on the contrary has caused its dissemination in a wider circle, especially in the poorer strata of society."

The editor of the *Social Hygiene Bulletin* may with propriety express his disagreement with these views; but we feel he has not been justified in his conclusion that the author condones or favors public prostitution, for we have not been able to discover a word or a line in the text of the article or in his conclusions that would justify the insinuation. Yet this is the substance of the editorial criticism above referred to, in which he refers to the author's views as "an exploded argument."

It seems to us the editor has utterly failed to catch the point of Dr. Wolbarst's article. We regard his article as an expression of conditions as they are, and not as he would like them to be. To us the situation is very much the same as that which exists with reference to the subject of prohibition. Prohibition is a law, and the national government and the various states are doing their utmost to enforce it. But where is the man who is foolish enough to say that while he believes in the righteousness of prohibition he is satisfied that prohibition actually is diminishing the amount of alcoholic liquors manufactured and consumed? Even the prohibition officers, whose duty it is to enforce the law, admit that "every little cellar has a still of its own," and that liquor is being manufactured and consumed clandestinely throughout the country in vast amounts, even by people who never tasted alcoholic drinks previously.

Why not look the facts squarely in the face? We do not believe in public prostitution, nevertheless we agree with Dr. Wolbarst in his view that the suppression of public prostitution has brought with it a vast amount of clandestine prostitution and loose living, which is a serious menace to the community, exactly as we believe that the clandestine manufacture and consumption of alcoholic liquors is a greater evil and does more harm to the morale of the community than all the distilleries and breweries ever did.

We feel Dr. Wolbarst has struck the proper note and has performed an actual service to the community in pointing out the hidden dangers of clandestine prostitution, which he traces, more or less

directly, to the suppression of the outward manifestations of public prostitution. Many entertain similar views, but evidently have not the courage to express them.

IS THE GOSSIP INSANE?

Men and women who gossip, said Dr. E. H. Bullock, of Chicago, city health director, cannot be in their right mind, and should be given the closest attention to get them back to normal. They have been called "assassins of character," and E. C. B. Jenkins, a psychologist and secretary to the Board of Police Commissioners, Chicago, says, in *The Detective*, February, 1921, that the neighborhood gossip and the anonymous letter writer have one of the nastiest, lowest and most vicious forms of insanity known to medical circles. Their distorted imagination visualizes scenes which they would have come true, and their insane mind immediately grasps the story and they repeat it as if it were true.

Gossip and anonymous letters are a constant pest at police headquarters, but reports registered with police officers in an attempt to injure character by these means or false telephonic reports are a failure; in fact, the police take more pleasure in tracking the informer than the one informed about.

ELECTROCUTION FOR UTAH.

The desires of Utah murderers will henceforth be limited as to modes of death. The shotgun execution law hitherto gave them the choice between hanging and shooting. When the latter was preferred the law provided five citizens at seventy dollars each. The list at the last execution was greater than at any other, so the Legislature thought it was bad morally, and repealed the shotgun for electrocution.

News Items.

C. V. Mosby Company's New Catalogue.—The C. V. Mosby Company announce the publication of a new ninety-six page illustrated catalogue of medical, nursing, pharmaceutical, and dental publications.

Seven Hospital Projects Approved.—Secretary of Treasury Mellon has approved seven hospital projects recommended by the board of consultants on hospitalization, for the treatment of former soldiers. They involve an expenditure of \$3,101,000.

Fordham Medical College Closes.—Fordham University's Medical College will close its doors and go out of existence when the present senior class is graduated on Thursday, June 16th. The college has a deficit of \$342,863, averaging \$21,429 a year for the sixteen years it has been in operation. Excluding from the total deficit \$180,000, representing the cost of the medical building, maintenance charges ran behind \$162,863, or a yearly average of \$10,179. New students have not been admitted to the college for two years, when it was decided that each department of the university must be self-supporting.

Harvard Raises Tuition.—An increase in tuition fees at Harvard University has been made necessary by an advance in expenses and an estimated deficit for this year of more than \$300,000. In the Medical School an increase from \$225 to \$300 will become effective with those entering next year, but will not apply to those already enrolled.

New Officers of the American Pediatric Society.—At its thirty-third annual meeting held in Swampscott, Mass., June 2d, 3d, and 4th, the American Pediatric Society elected the following officers for the ensuing year: President, Dr. Maynard Ladd, of Boston; vice-president, Dr. Percival J. Eaton, of Pittsburgh; secretary and treasurer, Dr. Howard C. Carpenter, of Philadelphia; editor and recorder, Dr. Joseph Brennemann, of Chicago.

Prize Essay Awards.—The New York Diagnostic Society announces the following prize essay awards for the 1920 contest. The subject was Group Diagnosis. The first prize of \$300 in gold went to Dr. F. Thompson Leys, the second prize of \$150 in gold was given to Dr. Clinton Lake Potter, and the third prize of \$50 in gold was awarded to Dr. Homer E. Smith. Sixty-one essays were submitted.

Insanity Increasing.—Dr. J. M. Lee, of Rochester, N. Y., before the annual convention of the American Institute of Homeopathy, declared insanity was increasing due to the world war and its aftermath. Methods of living, eating and the general hustle and tendency to worry and brood make for throwing mental machinery out of gear. Farmers were more susceptible to insanity than any other class, because they work hard, worry much and have little recreation.

New York and New England Association of Railway Surgeons.—The thirty-first annual session of this association will be held at the Hotel McAlpin, New York, on Saturday, October 29, 1921. Dr. Charles H. Mayo, of Rochester, Minn., will deliver the oration in surgery. The program will include a symposium on surgery of the stomach and duodenum. The officers of the association are: President, Dr. J. Frank Black, of White Plains, N. Y.; corresponding secretary, Dr. George Chaffee, of Binghamton, N. Y.

New York City Hospitals Rank in Class A.—Improvement in the efficiency of the city hospitals until all have been rated in Class A by the American College of Surgeons has taken place in the last three years, according to the report of Commissioner Bird S. Coler, of the Department of Public Welfare. The higher hospital standards were brought about by uniting all hospitals of the department under the supervision of a general medical superintendent, and by a policy of monthly conferences of the attending physicians of the various hospitals.

Gives Honor to Dr. Long.—Dr. William Crawford Long was officially recognized by the University of Georgia as the discoverer of anesthesia. This action was taken despite the decision of the Hall of Fame in New York, which recently awarded the honor to Dr. William Thomas Green Morton, of Massachusetts. The university authorities asserted they had evidence that Dr. Long first used ether for a surgical operation on March 30, 1842, four years prior to any other known record.

New Officers of the American Medical Association.—At the recent meeting of the American Medical Association, held in Boston, the House of Delegates elected the following officers: President, Dr. George E. de Schweinitz, of Philadelphia, Pa.; vice-president, Dr. Frank B. Wynn, of Indianapolis, Ind.; secretary, Dr. Alexander R. Craig, of Chicago (reelected); treasurer, Dr. William Allen Pusey, of Chicago (reelected); speaker of the House of Delegates, Dr. F. C. Warnhuis, of Grand Rapids, Mich.; trustees, Dr. Frank Billings, of Chicago; Dr. Wendell C. Phillips, of New York; Dr. Thomas McDavitt, of St. Paul, Minn. The next session will be held in St. Louis.

Medical Society of the State of New York.—At the annual meeting of the Medical Society of the State of New York, held in Brooklyn, May 3rd, 4th and 5th, the following officers were elected: President, Dr. James F. Rooney, of Albany; first vice-president, Dr. W. Meddaugh Dunning, of New York; second vice-president, Dr. William H. Purdy, of Mt. Vernon; third vice-president, Dr. William D. Johnson, of Batavia; speaker, Dr. E. Eliot Harris, of New York; vice-speaker, Dr. Dwight H. Murray, of Syracuse; secretary, Dr. Edward Livingston Hunt, of New York; assistant secretary, Dr. Wilbur Ward, of New York; treasurer, Dr. Seth M. Milliken, of New York; assistant treasurer, Dr. Charles Gordon Heyd, of New York.

Personal.—Dr. William Blair Bell, gynecological surgeon to the Royal Infirmary, Liverpool, England, arrived in New York recently to give a series of lectures throughout the United States under the auspices of the American Medical Association.

Dr. William A. White, of Washington, D. C., was elected president of the American Psychopathological Association, at its recent annual meeting.

Dr. John M. Swan, of Rochester, N. Y., has been appointed chairman of the upstate committee of the American Society for the Control of Cancer.

Dr. Hideyo Noguchi, pathologist and bacteriologist, Rockefeller Institute, was awarded the degree of Doctor of Science at the recent commencement exercises at Brown University.

Dr. W. G. Rows, of England, the noted neuropsychiatrist, attended the medical conventions in Boston where he read a paper on the biological significance of mental disease before the American Medico-Psychological Association.

Rear Admiral William C. Braisted was unanimously elected president of the Philadelphia College of Pharmacy and Science, at a meeting of the members held on May 9th. Admiral Braisted served on many vessels and in many naval hospitals, and was twice instructor in surgery in the Naval Medical School. He fitted out and equipped the hospital ship *Relief*. During the Russo-Japanese war he represented the Medical Department in Japan, and was decorated by the Mikado. During the world war the surgical, medical and pharmaceutical branches of the Navy were under his charge. He recently retired as Surgeon General and Chief of the Bureau of Medicine and Surgery of the U. S. Navy, a position which he had held since 1914.

Peking Union Medical College.—Plans have been announced for the dedication of the new buildings of the Peking Union Medical College, erected by the China Medical Board of the Rockefeller Foundation. The ceremonies will fill the week from September 15th to 22nd, and will include an international medical conference, to which scientists from America and European countries as well as from the Far East, have been invited. At the time will also occur the inauguration of the director of the college, Dr. Henry S. Houghton, and regular sessions of the institution's board of trustees, which is composed of representatives of the Rockefeller Foundation and of six missionary societies which had maintained an earlier medical college in Peking. The Peking Union Medical College comprises not only the medical school but also a two hundred and fifty bed hospital with outpatient clinics, a nurse's training school, and a premedical school, an institution of junior college grade with a distinct faculty and group of laboratory and classroom buildings.

Died.

BUZZELL.—In Standish, Me., on Monday, June 6th, Dr. Leonard O. Buzzell, aged seventy-two years.

CUNNINGHAM.—In Birmingham, Ala., on Monday, June 6th, Dr. Russell McWhorter Cunningham, aged sixty-six years.

DESSAU.—In New Rochelle, N. Y., on Saturday, June 11th, Dr. S. Henry Dessau, aged seventy-three years.

DINKELSPIEL.—In New York, on Monday, May 23rd, Dr. Edgar Dinkelspiel, aged forty-four years.

EDMUNDSON.—In Bethel, Tenn., on Wednesday, May 25th, Dr. Van O. Edmundson, aged sixty-six years.

FREI.—In Brooklyn, N. Y., on Sunday, June 12th, Dr. Emil Frei, aged forty-nine years.

GREEN.—In Martinsville, Ind., on Thursday, June 9th, Dr. Elijah V. Green, aged seventy-two years.

GROFF.—In Doylestown, Pa., on Friday, June 10th, Dr. James E. Groff, aged sixty-five years.

HOWELL.—In Philadelphia, Pa., on Tuesday, June 7th, Dr. Ellen W. Howell, of Middletown, N. Y., aged fifty-three years.

JANNEY.—In Riverton, N. J., on Wednesday, June 15th, Dr. Joshua D. Janney, aged ninety years.

JOHNSON.—In Pruntytown, W. Va., on Tuesday, May 31st, Dr. Charles F. Johnson, aged seventy-six years.

KELLY.—In Kellyton, Ala., on Thursday, June 2nd, Dr. John Baker Kelly, aged sixty-two years.

KNORR.—In Berlin, Germany, on Tuesday, June 7th, Dr. Ludwig Knorr, aged sixty-two years.

LONGYEAR.—In Detroit, Mich., on Thursday, June 2nd, Dr. Howard W. Longyear, aged sixty-eight years.

MCGAURIN.—In Newburyport, Mass., on Wednesday, June 15th, Dr. George D. McGaurin, aged seventy-one years.

MCINTYRE.—In New Albany, Ky., on Monday, June 6th, Dr. Charles W. McIntyre, aged eighty-one years.

MARTIN.—In Jamestown, N. Y., on Monday, June 6th, Dr. Orello S. Martin, of Salamanca, N. Y., aged seventy-three years.

PALMER.—In Mechanicsville, N. Y., on Wednesday, June 3rd, Dr. Frank A. Palmer, aged sixty-one years.

ROBERTS.—In Holmdel, N. J., on Wednesday, June 15th, Dr. D. Edgar Roberts, aged sixty years.

SCOTT.—In Aspinwall, Pa., on Monday, June 6th, Dr. J. Lorentz Scott, aged twenty-six years.

SCRIMGEOUR.—In Bridgeport, Conn., on Wednesday, May 11th, Dr. Arthur Scrimgeour, aged thirty-eight years.

SPICER.—In New York, on Monday, June 6th, Dr. William Henry Spicer, aged fifty-six years.

STILL.—In Johnstown, N. Y., on Tuesday, May 31st, Dr. David Vedder Still, aged sixty-six years.

TUCKER.—In Nobelsville, Ind., on Monday, June 6th, Dr. Frederick A. Tucker, aged forty-nine years.

LONDON LETTER.

(From our own correspondent.)

Fellowship of Medicine—Influenza in France—The Crisis at King's College Hospital—The Dreadnought Hospital—Bad London Milk—Dr. Adami on Malaria—Need for More Houses—Professor F. G. Hopkins Made Sir William Dunn Professor of Histological Chemistry at Cambridge—Honor for an Irish Doctor—Obituary.

LONDON, May 27, 1921.

For some time efforts have been made to bring about an arrangement between a London hospital and the Fellowship of Medicine for postgraduate teaching. It is now understood that a draft memorandum has been drawn up by representatives of the Fellowship and members of the staff of the Great Northern Central Hospital. The object is to associate the hospital with the Fellowship, and so to make of it a kind of Mecca of British medicine, which may be visited by medical men from America and other countries who desire to study our methods and to improve their knowledge. If it comes to pass, it will be for the good of the hospital. On the other hand, such an arrangement will in a high degree benefit the Fellowship, as the hospital enjoys a great and well deserved reputation, and its physicians and surgeons include some of the most capable and progressive minds in modern British medicine.

Although the postgraduate scheme in connection with the Fellowship of Medicine appears to lag somewhat, there are signs now that progress is being made with this scheme initiated by that great organizer, Sir John MacAlister, secretary to the Royal Society of Medicine. Money is needed to render the postgraduate medical teaching movement in London a complete success, and if the London medical profession hope to make of London a medical centre capable of competing successfully with Berlin and Vienna, not only must funds be forthcoming with reasonable promptitude but every effort must be made to assist Sir John MacAlister in his task of organization. The coöperation of the Great Northern Central Hospital is a step in this direction.

* * *

It has been announced recently that the authorities are manifesting concern over the spread of the influenza epidemic, which is not confined to military establishments, although the death roll is heaviest among soldiers. At the Bégin Military Hospital, which serves the garrisons in the Paris district, there are said to be two hundred cases. M. Barthou, War Minister, describes the outbreak as rather violent and has taken measures to arrest its progress. More deaths have occurred among the young soldiers of the Orleans garrison, where there are one hundred and fifty influenza patients, for the most part suffering slightly. The cases in the Saint Etienne barracks number sixty and at Bourges, where there have been some fatal attacks, there are three hundred men in the military hospital. Soldiers have died in hospital at Albi, where there are cases among civilians.

Another report says that numerous French military barracks at present occupied by young recruits of the 1921 class, who by common consent show an exceptionally fine standard of physique, have been attacked by an epidemic of Spanish "flu." According

to the medical officers dealing with the outbreak, the disease has been spread mainly by bugs, which seem to have invaded the barracks in large numbers. Energetic measures are being taken to combat the epidemic, but there have been several deaths recorded at Orleans and in the military hospital of Le Puy.

* * *

The following statement has been issued by the committee of King's College Hospital, London. "In the expectation that Lord Cave's committee would make some generally acceptable proposal to relieve the financial position of the London hospitals, the committee of King's College Hospital has refrained from taking action to meet the position in which the hospital stands; but they have now been obliged, regretfully, to come to a definite decision. At the end of 1920 the debt was £80,000 (\$400,000), for which the only security was investments of the present value of about £20,000 (\$100,000). Since then it has been increasing at the rate of about £1,000 (\$5,000) a week. At present the income does not show any appreciable signs of expansion, though the committee look forward with confidence to some substantial result from the systematic support in small contributions from large sections of the community served by the hospital. The committee, although they have already a waiting list of nearly 1,000, have been impelled, in the hope of avoiding a worse disaster, to refuse for the present to take any more inpatients until the number of occupied beds is reduced to 200. As accommodation is thus released they hope to make arrangements so that the vacant beds may be used as a means of obtaining additional income by the provision of accommodation for paying patients."

The above has been quoted as a typical instance of the difficulty in which big British hospitals are at the present time and as showing that those responsible for the management thereof are coming round to the pay system or partial pay system. State control is an abomination to medical men and the majority of the laity alike, so that other means must be found to place the hospitals on a sound financial basis. Good organization is doubtless one of these means.

* * *

The Dreadnought Hospital for Seamen celebrates its centenary this year and in view of the fact and of the good work done in it it may be of interest to American readers to give a brief account of this institution.

The Seamen's Hospital Society, which is responsible for the hospital, was founded in the winter 1917-18 to provide temporary relief to the great number of distressed seamen who were at that time to be found in the streets of London. In 1821 a hospital was set up aboard the *Grampus*, a fifty-gun ship, moored off Greenwich. In 1830 the Government provided a larger ship, the *Dreadnought*, 104 guns, from which the present hospital takes its name. In 1870 the hospital moved ashore into the old Infirmary of Greenwich Hospital, where, after reconstruction on modern lines, it still carries on its benevolent work among seamen of all nations. A branch hospital in the Albert and Victoria docks now contains fifty beds and a large outpatient department.

The work of the institution is supplemented by that of two important medical schools, the London School of Tropical Medicine and the London School of Clinical Medicine. There is also a postgraduate school at Greenwich, to which a number of naval surgeons are assigned each session. In the connection it may be remarked that so far as tropical medical teaching is concerned, London is far ahead of the European medical schools. The London School of Tropical Medicine is, with the possible exception of that of Liverpool, the most complete in every respect in the world. Moreover, it has plenty of material and its staff is second to none.

* * *

A bacteriological examination of fifty samples of milk, carried out by Dr. F. H. Teale, of University College Hospital for the St. Pancras Borough Council, revealed serious contaminations in the milk ordinarily used throughout that borough. On the analyst's report the medical officer of St. Pancras stated that the eighteen samples of farmers' milk as delivered at railway stations "are almost without exception bad," as judged by a given standard and that samples taken at milk shops and on milk rounds are "definitely worse," indicating "a further stage in the ill effects of bad methods of transportation and storage, lack of cleanliness and the keeping of milk at too high a temperature." Dr. Shaddick Higgins, the medical officer, in agreeing with the analyst as to the precautions which should be taken, stated: "I have no hesitation in saying that the present system whereby the milk is passed from vessel to vessel and handled under unsuitable conditions is thoroughly bad." The St. Pancras Borough Council have already made representations to the Government that in the interests of the cleanliness and purity of the milk supply of London, the provisions of the Milk and Dairies' Act, 1915, should be brought into immediate operation. The committee declare that the result of the bacteriological examinations strengthens the case of the Council in favor of a purer milk supply being enforced.

America is a long way in advance of Great Britain as to regulations for the guarding of milk from infection and contamination. Transport of milk by railway in this country is inadequate and defective and the care of the milk after it reaches its destination by rail is by no means up to the mark. Some few years ago a series of articles were contributed to the *Lancet* dealing with the milk supply of London, but little improvement in this direction has been witnessed in London.

* * *

Dr. J. G. Adami, Vice-Chancellor of Liverpool University, delivered recently a health lecture in London, in which he drew attention to the fact that though it had been abundantly proved that malaria was due, not as was at one time supposed to miasma arising from the low lying ground, but to mosquitos, and that the progress of the malarial bacteria could be arrested by pouring oil on the stagnant waters. So difficult was it to destroy deeprooted tradition that there were still many people in Cambridgeshire who did a thriving business in supplying the country folk with their weekly bottles of laudanum as a sup-

posed safeguard against malaria. He added that General Allenby won one of the most brilliant victories of the whole war against the Turks mainly through his knowledge of the incubation period of the disease.

Warning the audience against the terrible racial effects of venereal diseases, he expressed the view that the majority of the cases of rheumatoid arthritis that occurred during the war were of venereal origin, and he strongly advocated the adoption of preventive precautions, not for the sake of impurity for the selfish indulgence of uncontrolled passions, but in the interests of posterity.

* * *

Speaking at the Housing and Town Planning dinner, Dr. Addison, late Minister of Health, said that although there had been a change of office, the Government had promised that there would be no change of policy as regarded the housing question. But he advised the public to keep the Government up to their promise. Some £14,000,000 was spent in dealing with tuberculosis, which was very largely a result of bad housing conditions.

* * *

Prof. Frederick Gowland Hopkins, professor of biochemistry at Cambridge University, has been elected Sir William Dunn Professor of Chemistry in Cambridge University. Professor Hopkins is well known for his investigations into and discoveries with regard to the vitamins.

* * *

King George has been pleased to approve that the honor of knighthood be conferred upon James Craig, Esq., M. D., F. R. C. P. I. Sir James Craig is one of the best known medical men in Ireland, where he holds many public appointments. He is king's professor, professor of medicine at Trinity College, Dublin, president of the Royal College of Physicians of Ireland, physician in ordinary to the Lord Lieutenant, physician to Sir Patrick Dun's Hospital, Dublin, and consulting physician to various institutions. He received his medical education at Trinity College, Dublin, and took his degree in 1885. Since that date there are few of the more important posts of the profession in Ireland which he has not filled. He was general secretary and editor of transactions of the Royal Academy of Medicine in Ireland from 1904 to 1910. Sir James Craig is also an extensive contributor to the literature of the profession.

* * *

The death is announced of Mr. Henry Juler, F. R. C. S., the well known ophthalmic surgeon. Mr. Juler was the son of a medical man, Dr. H. C. Juler. He was educated in London, Paris and Berlin, and was a student at St. Mary's Hospital, London, as well as at various Continental schools. He became medical superintendent of St. Mary's and pathologist to the Royal Westminster Ophthalmic Hospital and consulting ophthalmic surgeon to St. Mary's. He wrote several works on the eye, including *A Handbook of Ophthalmic Science and Practice*. He was widely known and highly esteemed, both as a surgeon and as a man.

Book Reviews

KEEN'S SURGERY.

Surgery, Its Principles and Practice. By Various Authors. Edited by WILLIAM WILLIAMS KEEN, M.D., LL.D., Emeritus Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College, Philadelphia. Volume VII, with Three Hundred and Fifty-nine Illustrations, Seventeen of Them in Colors. Volume VIII, with Six Hundred and Fifty-seven Illustrations, Twelve of Them in Colors. Complete *Index to Keen's Surgery*, Volumes I to VIII. Philadelphia and London: W. B. Saunders Company, 1921. Vol. vii, 855; vol. viii, 960; Index, 182.

These volumes complete Keen's great surgical masterpiece. The six preceding volumes, reviewed in this journal at the time of their publication, recorded the progress of surgery up to 1913. Then with the onset of the great war came its surgical problems and their solution—all of which constitute in themselves a most remarkable contribution to the art and science of modern surgery. The advances in surgery, which resulted in consequence of the vast human slaughter in the great conflict, are embodied in the two volumes under consideration.

Volumes VII and VIII are distinctly products of the war—not war babies, but war giants—which have made available for the surgery of peace what has been learned in the crucible of war. The outstanding lesson we have been taught is that modern surgical principles have been tried and not found wanting. The great principle enunciated by Pasteur and Lister, that infection is caused by bacteria and can be overcome only by removing or destroying them, was established for all time, more firmly than ever, with the complete vindication of Pasteur and Lister.

This is made strikingly evident by the fact that Keen found difficulty in obtaining an author to write the chapter on tetanus. Most of the surgeons who had served in the war had seen not more than one or two cases, and many had not observed a single case. Typhoid, like tetanus, the scourge of past military conflicts, was practically unknown, except for the first few months of the war.

Professor Keen comments with evident bitter memory on the German violations of the rules of mercy and humanity in warfare, and replaces the ancient classic *Fides Punica* with *Fides Germanica*—a title richly deserved.

In a work of such stupendous proportions and general excellence, it is difficult to select for comment or praise any particular author or his contribution. Most of the subjects have been treated by surgeons of international repute, whose names

are at once a guarantee of high scientific learning and practical experience.

A few of the outstanding chapters might be mentioned: Volume VII contains an unusually fine chapter on inflammation, by Adami; syphilis and surgery of the skin, by Schamberg; traumatic shock, by Cannon; fractures, by Eisendrath and Straus; gunshot fractures, by Blake; orthopedic surgery in civil life, by Lovett. The articles on military surgery in its various phases are exceedingly well written and constitute a distinct addition to our knowledge of the horrors of warfare and the surgical means of mitigating them. The illustrations are most illuminating, and many of them bear official governmental sanction, having been loaned for the purposes of this work by the British Admiralty.

Volume VIII contains forty chapters, each covering a particular topic by its own author. Endocrine surgery covers six chapters, well written by such well known surgeons as C. H. Mayo, L. B. Wilson, Kendall, Mann, Adson and Vinson. Neuhof contributes an excellent chapter on the surgery of the head; the abdomen and pelvis are considered by Crile; Deaver and Pfeiffer present the subject of appendicitis; Bransford Lewis has written interestingly on the bladder and the ureters, and E. L. Keyes, Jr., on the external male genitals, including a rather inadequate consideration of gonorrhoea; radium in cancer and other diseases is discussed rather fully by Duane and Greenough, and the x ray by Cole and Steiner. Anesthesia in its various aspects is fully treated. In addition there are interesting chapters on the legal relations of the surgeon, and the American Red Cross in war and peace.

A desk index, in a bound volume of 182 pages, completes this most excellent work. Even a cursory reading of these volumes must give the student or practitioner the sensation of having touched the heights of our surgical knowledge of the present day. American surgery can boast of nothing finer or more worthy of a permanent place in surgical literature than this monumental work of Professor Keen. The timeliness of adding these two volumes at the present moment is important. The surgical procedures developed during the war have been studied and presented after mature deliberations.

This distinguished master, his coworkers, his publishers, and the American medical profession generally and severally, deserve to be complimented on the successful termination of their combined efforts.

WILLIAM WILLIAMS KEEN,
Editor of *Surgery, Its Principles and Practice.*

STEKEL.

Die Geschlechtskälte der Frau. Eine Psychopathologie des Weiblichen Liebenslebens. Von Dr. WILHELM STEKEL, Nervenarzt in Wien. Wien: Urban & Schwarzenberg, 1920. Pp. viii-402.

Die Impotenz des Mannes. Von Dr. WILHELM STEKEL. Berlin-Wien: Urban & Schwarzenberg, 1920.

It does not matter from what angle these two books of Stekel are approached. Any consideration of them reveals rich material. Stekel is a writer who handles his subjects in a lavish manner; lavish, but with that restraint which bends all to the urgency of his themes. He evidently approaches his clinical work with the same exuberant interest. There he reaps through psychoanalysis a rich harvest of results. He has collected these results and presented them for the dissemination of such knowledge of the sexual disturbances as he has thus obtained. Stekel evidently has approached literature and other cultural fields of interest in the same way. His acquaintance with these fields both broadens and strengthens his conception of the more technical human problems that form the subjects of his writings here. It gives his work that literary character which always belongs to his most professional treatises. There is also a high moral tone to his work, and through it a sort of determined optimism that the race must and shall better its suffering condition through greater knowledge of the underlying factors of the suffering. The evidence of forceful adherence to such determination in these reports of his work reveals the spirit in which he approaches that work through patient as well as through reader.

It is important in approaching his writings that special emphasis is laid upon them from the professional point of view. For it is not first for their literary character nor their mere force of presentation that they are valuable. At the same time, one will not find any such limitation as the titles of these two volumes of his series might suggest to the less thoughtful reader. They are no mere formal collection of statistics compiled from a routine review of case histories. Nor, on the other hand, will they afford a mere opportunity for an inquisitive revel in sexual details. Sexual details there are in abundance, but any superficial interest would be soon transformed into a conscience stirring realization of the terrific importance of the factors that are playing havoc in the domestic and social adjustments of men and women and the necessity of taking them frankly into account. Stekel has unearthed many facts, he has disentangled many snarls which are all too common, not in a few men and women in a far away city, but in all the lives of the members of civilizations.

There are faults in these books which might be attacked from various angles. Some lie in that very exuberance of personality and its expression which one finds otherwise commendable. At times the matter in hand might gain in force were the writer himself a little more effaced. Yet because this is so largely a fault of his dynamism one cannot seriously quarrel with it. Occasionally there may be detected some personal weakness of criticism of fellow workers in which the author does not invariably add to the weight of his own position. It is not always so, but a somewhat purile note of com-

plaint creeps in in which the writer's own position is not each time well established. There is some unnecessary and rather mistaken effort to claim first discovery in one or two instances, or complaint that such has been plagiarized by some one else. Again, as in the chapter on *ejaculatio præcox* in the second book, Stekel has not proved his position as of any advantage over that of Abraham, which he condemns, or any better established. It is the same in his disagreement with Freud over the interpretation of fundamental causes to be found in infantile factors and other such technical points. Of course, to enter carefully into these criticisms would bring up the whole controversy which has waged in the psychoanalytical circles of Vienna. Such need not press itself specially upon our attention, nor could one here be in the position to pass complete judgment even in strictly technical points.

Surely it is not necessary in the face of these valuable contributions to the literature of psychoanalysis. In spite of the slight suggestion at times of a personal animosity in comparison in spite of a somewhat dogmatic method of stating Stekel's own conclusions, one is carried on by the far more important positive values of the books. One can also recognize with satisfaction for the genuine interests of psychoanalysis the grateful deference with which Stekel takes pains to acknowledge all his debts to the originator of the psychoanalytical method. This is true even though one must sometimes smile at the overcompensatory character of this deference when it follows upon a derogatory comparison of method and result. In fairness to psychoanalysis one must ask also whether some of Stekel's work is not the result of his forceful personality, and is therefore not always completely psychoanalysis. This can be said without denying that he understands psychoanalysis as a method really of analyzing and so employs it. He has given rich proof of this in his published cases. Yet there is often also, or in place of this, a strong note of authoritative advice and direction. To be sure, he admits that at times he chooses such means, and he has discussed freely the use of distinctly other therapy than psychoanalysis. At times, however, he seems not to have kept sufficiently clear the distinction of psychoanalysis as such.

The book that roused no criticism would be of little worth. If, therefore, it has been sufficient to set the reader to weighing for himself the writer's rapidly flung statements in which he propounds his own opinions of method and his own conclusions, the task may be resumed of commenting upon the most valuable material gathered in these thick volumes. Facts are there in great number. They cannot be gainsaid. Stekel's own evaluation of such facts and his earnest plea for their consideration, both by the medical profession and by the society of men and women where these facts exist, can speak only for themselves to the truly conscientious reader.

There is not much in these books that the psychotherapist can afford to pass over. Voluminous as they are, their material needs detailed attention, both from one practically engaged in the work in which Stekel takes so prominent a part and from

any one genuinely interested in the restoration of the lives of men and women to healthful social functioning. Stekel makes some announcements which may be startling at first sight, but when they have been pounded home through page after page of illustration, the reader is left convicted of a responsibility for himself and for society. He must deplore that they have been too long passed over in ignorance and that still they meet with so much timid opposition.

Stekel has made his fundamental statement in the opening of the former of these two volumes. This he reiterates again and again, chiefly as he forces upon us one case after another in which his statement has shown itself disastrously true. Then he pleads that help shall come for this prevailing disastrous condition through an adjustment of civilization to the needs of the individual in the light of this fundamental fact. His statement reads: "We assert firmly the distressing truth: The majority of men standing at the higher cultural level are relatively impotent; the majority of women from the same social level are sexually frigid!" He asserts again and again that this sexual impotence—we may apply the term to the female frigidity as well—is a psychically determined condition. There is particular need of such frequent assertion, especially in regard to male impotence, because there has been so much effort to find any one of a variety of causes for the phenomenon. The patient has done it on grounds which he has rationalized out of his conflicts; medicine has devised explanations and treatment out of a disregard of the vast play of psychic forces, largely unconscious, which have manifested themselves for one hidden reason or other in the patient's life.

This fundamental statement is, after all, only one of a number of truths which punctuate the writing of the books. They are almost aphorisms in form, but are saved from a too abstract terseness by the fact that they are pregnant facts wrested out of repeatedly related experiences, human, personal, intense. They drive home the inescapableness of the problems; they present vividly the various points at which the problems manifest themselves; they stress the importance of sex efficiency in determining health in the lives of men and women. Stekel takes the trouble, first of all, to define what love is to the individual in its various manifestations and what it should be if these were better understood. For then these partial manifestations, which deceive the individual, would be seen in their full meaning as related to the inner life and to external things in the individual experience and as only factors of complete love and distortions of the love instinct. The whole would be found to be something more than these. It would be found that this whole was grounded and centered in sex expression.

Somewhere in the latter of the two books Stekel speaks of an antisexual instinct at war with the sex instinct. By this he means that will to power which he describes in the earlier book, and continually refers to throughout all his reports. This interferes with the complete surrender to sex enjoyment. It results in an instinctive strife which exists between man and woman. Is not this the particular manifes-

tation in the sex relationship of the distinction to which Freud calls attention when he reminds us of the strife between the ego instinct and the creative libido, "ego-libido and object-libido," as he calls it? Stekel finds it a most important principle to be borne in mind when searching for the factors underlying impotence and frigidity; in fact, in following out the whole conflict by which man and woman through life have built up a resistance to the free yielding and therefore the free expression of self. It is found operative in earlier relationships of life and then in the sex relation. Stekel says: "Two bipolar forces strive for mastery in the human psyche, the will to power and the will to subjection. This bipolarity of feeling forms the basis of the perfect relation of man and woman, but there may be unconscious conflict in the nature of either or both against accepting the role of either feeling." In the woman, then, "the desire for mastery can be more important to her than the pleasure of being satisfied; the feeling of personality of greater significance than the strength of sexual sensation." The woman cannot give herself to her sexuality because deeply hidden in her unconscious she will not. The man, too, may be hindered by this deeper will of which he does not know from carrying out his apparent sex need. In both man and woman love has been replaced by unconscious hate. Many times analysis shows how his "will not" is further entangled with defensive wishes against the force of some of the components of his sex wishes, chiefly the sadistic components, sometimes in its most extreme forms. Both men and women are afraid to give way to the strength of the desire, the passion they feel within themselves. Of course, this is largely due to the fact that they do not understand the component erotic forces of which the passion is composed. This often means that such separate components are strengthened in early life. Infantile wishes, retained in infantile fixations, homosexual reversal of the roles, all the factors known from psychoanalysis are found to be operative in withholding the libido from the complete performance or acceptance of the sex act.

Stekel asserts that he does not lay such exclusive emphasis upon the infantile factors as Freud does, nor does he believe it necessary, in many cases, to proceed so far back in a life to correct these sex difficulties. He makes this point particularly in reference to the treatment of impotence in the male, where often some comparatively recent inhibition acts as a moral guardian through prevention of a forbidden sex act. Sometimes, again, it negatively serves the forbidden wish by inhibiting function in both permitted and unpermitted situations. These instances serve as illustrations of the exceedingly numerous and varied complications which result when the personality is torn by conflicting wishes. The bringing of these into consciousness by psychoanalysis brings the personality back to a unity of action. Potency returns with a readiness which disproves the validity of the organic or otherwise rationalized causes attributed by the patient or physician to the previous condition. Of course, there are cases greatly complicated by stubborn factors of resistance built for a long time into the

patient's psychic life where the will to an adjustment is not present, where the patient does not want to give up the sources of his conflict, just as in all psychoanalytical or other medical experience. In spite of this Stekel is able to report a striking array of cases of often sudden and complete return of male potency and readjustment by the woman with understanding and acceptance of her sex life.

One is impressed with the pervasion of these conflicts by infantile factors and experiences of early life, even though Stekel avoids laying what he considers too exclusive emphasis upon them. His discussion of the infantile or regressive type of reaction to life, as over against the thoroughly adult type of adjustment, is clearly stated in more than one place and in that peculiarly picturesque manner whereby he makes his statements crisp and vitally telling. He devotes special attention also to the traumas of adulthood, showing that these play an important part in the sexual inhibitions which result in impotence and frigidity. He speaks of these in a separate chapter in the book devoted to the woman's difficulties, and lays special emphasis upon the reaction to the first sexual experience as determining largely the later reaction. He himself says that this pertains to men as well as to women. Anxiety concerning the first coitus and further fear of the bondage of the marriage relationship are often unconscious determining factors of impotence. Stekel warns particularly against neglect of the unconscious religious factor in the lives of patients.

Such are some of the many complicated facts revealed at work hindering the fundamental functioning of lives. Long analyses are given, sometimes long selfconfessions in the form of written histories by certain patients themselves. Here is the feminine counterpart of Don Juan, again the female homosexual. There are corresponding illustrations of these and other types of diversion of the sex life in the male. In all the background is relatively the same. There are the conflicts set in the early family life, the contradiction of conflicting impulses, the neurotic reactions. All are manifestations of the struggle of the sex impulse against conditions of cultural life. For this has failed to allow for the strength of the sex life with its need for complete realization in an expression which can absorb the whole personality. Stekel summarizes the conflict now and again in one of his pregnant sentences. It is the struggle between the psychic and the physical love, a conflict which can be solved, he continually urges, only by a complete union of the two. To this end he works in his individual analyses, to this end he urges society to make less exacting conditions for the complete relation of man and woman. Again, he states it as the conflict between the brain and the spinal cord. In the interests of culture the brain has forgotten the needs represented by the spinal cord and has imposed conditions impossible of fulfillment. Stekel does not plead for license, but for a freedom for love to find and retain its own. He does not believe that true love can have more than one object at a time. He does allow for the transfer of love in the changes that life inevitably brings. Here he believes that social sentiment should enlarge itself to recognize the underlying need

and the facts that do exist in this deepest relation of man and woman. The rigid social bondage, where love has ceased to exist, he believes to be an immoral relationship, which could be exchanged for the true love which both the man and the woman need. Yet behind these statements of this principle lies something which can reassure society against fear of domestic collapse. Stekel's own healthy comprehension of true love and his experience of the readjustments made by his patients, when their difficulties and their possibilities for true love came to be understood, show that true love can be established and maintained. Once the inhibitions are removed, their sources in conflicting impulses brought to light, love has something far more than the initial passion and the mere physical need, strong and broad as that may be, for its constantly varying adjustments and its maintenance upon them. If society would lift its pressure of timid selfdefense, elasticity of health for the family, society and the individual would result.

The problem is not presented, however, in such mere Utopian simplicity. There are chapters demanding searching thought in which the author discusses the question of woman's needs, her striving through the many avenues of today for something more than a mere physical bondage to sex. She demands the complete union of physical and psychic love. The problem of childbearing in its relation to her love life, as well as to that of the man, and also its economic aspect, is taken into account. Stress is laid upon the great danger to society as well as to the individual in the single child marriages, or those with perhaps two children. They are productive of neuroses in the younger generation, and this matter forms a serious phase of the actual sexual question, whether considered individually or in relation to the results to society. The consideration of the devastation wrought by the war in further straining the relations between men and women and strengthening of the homosexual bond also bears special reading.

These social presentations of Stekel's subject are so pressing and offered with so much stimulus to serious thought that there is danger in review of passing over the more strictly medical value of the book. The discussion of these sexual problems has been approached from several points of view in which the physiology of the disturbances has been most simply but clearly discussed and always with its relation to the psychic factors inextricably bound with the physiological manifestation. This is true chiefly in the book on male disturbances, since in these the physiological effect is conspicuously in evidence. A special chapter on physiology treats of these physiological phenomena of sex disturbance, while a chapter on pollution has been contributed by Dr. Tannenbaum of New York. The relation, or, rather, the supposed relation, of masturbation to impotence receives especial treatment, since this has occupied so large a place in medical thought of the past and still more with the laity themselves. Ejaculatio praecox and impotentia paralytica are given separate chapters, and are followed by a still further discussion of the disturbances of the organism in its different forms and degrees.

Practical Therapeutics

ENDOCRINOTHERAPY IN SKIN DISEASES.

By MOSES SCHOLTZ, M. D.,
Los Angeles, Cal.,

Dermatologist to the Post-Graduate School, Los Angeles, Medical Department, University of California, Los Angeles County, and Kaspere Cohn Hospitals.

The subject of endocrinology grows from day to day in importance and interest to the clinician and to the research worker. A voluminous literature has grown up on every phase of the subject in its clinical and experimental aspects, yet one is struck by a surprisingly scant reference on the clinical application of endocrinology to dermatology. Among very few data found in the literature, I wish to acknowledge most excellent contributions by the American writers, Foerster (1), McEwing (2), and Montgomery (3). This paucity of dermatological data is particularly strange, since the dermatological syndrome, myxedema, was one of the first clinical phenomena that attracted the attention of clinicians to the endocrinous system.

TROPHONEUROTIC INFLUENCE OF ENDOCRINOUS GLANDS ON THE SKIN.

The problem of outlining the possibilities of endocrinotherapy in skin diseases can best be approached through considering the interrelationship between endocrinous glands and the skin. This relationship in its turn can best be seen through a study of the enormous clinical field limited by dermatological syndromes, myxedema at the one end and hyperthyroidism at the other.

HYPOTHYROID SKIN.

In myxedema, the extreme type of hypothyroidism, the skin is pale, thick, pasty, cold, dry and harsh, does not pit on pressure, and presents a dead, muddy, yellowish and waxy appearance. In mild chronic cases of hypothyroidism, which can be considered as abortive cases of myxedema, one sees dry, harsh skin with a tendency to scurfiness, a branlike exfoliation, a tendency to chap, eczematization, malar flush, cutaneous chilliness, nail dystrophies, dry, lustreless hair and alopecias, particularly of the outer third of the eyebrows.

HYPERTHYROID SKIN.

On the other hand, in hyperthyroidism one sees thin, perspiring, easily flushed skin, urticarial attacks, erythemas, pigmentations, dystrophies of the nails, alopecias and eczemas; the hair is thin and glossy, the complexion is clear. What a striking illustration this presents of the powerful and all pervading influence of the thyroid on the nutrition and function of the skin. A physiological exuberance, glandular hyperactivity, and maximum of functional and nutritional activity on the one hand—hyperthyroidism; and, on the other, a slowing down of all functional activity, gradually increasing tissue degeneration culminating almost in a total cessation of the cellular activity and normal function of the skin—myxedema.

Between these two polarities a countless number of transitional clinical forms are to be found. These cases, presenting one, two, or many of the hypothyroid skin features in various combinations and varying infinitely in the degree of intensity, form numerically a large group of dermatoses with clinically variable pictures. The clinical importance of these transitional forms collectively easily overshadows that of well developed cases of myxedema, because clear cut cases of myxedema are so rare and so characteristic as not to escape recognition. On the other hand, mild hypothyroid dermatoses and abortive myxedematous cases are common, and easily escape recognition unless the clinician is aware of their existence and is constantly watching for them.

It is of great interest to note that some of the dermatological symptoms, such as pigmentations, alopecias and eczemas, may occur both in hyperthyroid and hypothyroid syndromes. These apparently selfcontradictory findings are to be accounted for by a clinical phenomenon on which all endocrinologists agree; that the hyperactivity of the thyroid may go on at certain times simultaneously with a hypoactivity. As has been pointed out so well by Rogers (4), most of the hyperthyroid cases begin as hypothyroid, where the enlargement and hyperactivity of the gland develops as a compensatory but imbalanced effort. Thus an intermediate stage develops, which shows a coexistence and mixture of both hyperthyroid and hypothyroid skin symptoms.

OVARIAN AND GONADAL INFLUENCE.

While the trophoneurotic influence of the thyroid system is the most striking among endocrinous glands and can be presented in a concrete and tangible manner, other members of the endocrinous system exert also a powerful influence on the function and nutrition of the skin. Gonadal and ovarian hormones come next after the thyroid. Their influence on the function and nutrition of the skin is best manifested at the two physiological transitional epochs of an individual, the awakening of the puberty and the climacterium, both in the male and in the female.

The first period of physiological awakening is associated with a heightened secretory activity of the sebaceous glands, clinically manifested by seborrhea and acne vulgaris of adolescents. At this time the skin is at its highest physiological level of nutrition, shown by the exuberant increase of the vitality, gloss, tone, elasticity and flexibility, and the growth of the hair. On the other hand, climacterium in both sexes induces a progressive decline of all physiological qualities of the skin—elasticity, gloss, oily and velvety feel, with a gradual development of pigmentation, keratoses, and other features of senile atrophic degeneration. In the female these atrophic skin changes are commonly preceded by variously manifested clinical disturbances of the vasomotor apparatus of the skin, in the form of

generalized flashes, erythemata and urticarial efflorescences.

ADRENOTROPISM.

An extremely important trophic centre controlling the skin pigmentation, both in its physiological and pathological manifestations, is being more and more relegated to the so-called chromaffin system of the suprarenal gland. The basic clinical syndrome of bronzelike discoloration, established by Addison, has been extended and broadened by the latest research. Abel (5) has demonstrated in the pigment deposits of the skin a blood pressure raising substance analogous to adrenalin.

Kaplan (6) establishes a doctrine of endocrinotropism, believing that pigment deposits in the skin are made up of melanoblastic cells of the chromaffin tissue and connects them embryologically with the sympathetic nervous system. These chromaffin cells are found in the adrenal medulla and yield epinephrine. Kaplan believes that the appearance of blackish or brownish spots does not necessarily suggest grave pathological changes in the suprarenal glands, but it does point to an increased activity of the adrenal system, most likely of a compensatory character. Casual reports of vitiligo patches by suprarenal glands are also suggestive of the trophic control of the adrenal system of the pigmentation of the skin.

INDIRECT RELATIONSHIP OF ENDOCRINES TO DERMATOSES.

Beside a direct trophic relationship between the endocrine glands and various dermatoses, an indirect relationship of the same nature can be observed and established in a great variety of clinical forms. Thus, disturbances of the pancreas may lead to diabetes with its train of glycosuric dermatoses—furunculosis, eczema of the genitals, xanthoma, pruritus, and gangrene. The dysfunction of the pancreas, or any other digestive endocrine, may lead to various dyspeptic disorders with subsequent gastric or intestinal retention, fermentation, and intoxication leading to toxic erythemata, urticarias, eczematata or acne rosacea. In a similar way diseases of the hemopoietic endocrine system—the lymphatic glands, the spleen and the bone marrow, may lead to various dermatoses of a leucemic type. Beside the true lymphogranulomatous tumors of the skin, the various nonspecific dermatoses, such as eczemas, pigmentations, prurigos, exfoliating dermatitides, and purpuric lesions, belong here.

VASOMOTOR ENDOCRINE DERMATOSES.

The enormous domain of vasomotor dermatoses comprising various symptomatic or idiopathic toxic erythemata, dermatographism, local angioneurotic edemata, urticarias, erythromelalgias, acrocyanotic conditions, Raynaud's syndrome, so-called idiopathic skin gangrene, and hyperhidrosis, presents a striking illustration of indirect activity and participation of endocrinous glands and sympathetic nervous apparatus. The participation of the endocrinous system in these cases may be wholly incidental and be merely one of the many symptoms of underlying toxemia, infection or emotional play. One of the most striking and illustrative cases of this character I have seen occurred in a tuberculous patient, in an advanced stage of the disease, who had recurrent arterial erythemata, lasting for several days, of the

right half of the head, neck and right arm, corresponding strictly to the anatomical distribution of the right branches of the vagus. In cases of this type endocrine dermatoses may be an early or the only symptom of the latent infection or toxemia, and their proper interpretation may be of great diagnostic value.

HYPOTHYROID SKIN.

In considering the possibilities of the clinical utilization of endocrinous principles in dermatology, one is easily brought to the belief that the thyroid system offers the most tangible and definite clinical facts for the purpose. The profound skin changes induced by hypothyroidism, as they unfold themselves to the clinical observer in a gradual scale from its extreme expression, myxedema, to its clinical antipode, hyperthyroidism, can be conveniently classified in three groups: 1, effects on the secretory activity of the sebaceous glands; 2, effects on the processes of keratinization; 3, effects on the nutrition and growth of the hair.

The diminution and slowing down of the secretory function of the sebaceous and sweat glands is the most characteristic and constant feature of the hypothyroid skin. The resulting dryness of the skin entails a secondary development of a characteristic syndrome of scurfiness, tendency to follicular keratotic plugs, chapping, itching, eczematization, cracks and fissures, and chilliness. This syndrome is of the greatest diagnostic value, as an early sign of a mild hypothyroidism, and should be more appreciated by the general profession.

Another constant feature of a hypothyroid skin is a slight thickening and desquamation of dry epidermic scales, pointing to the interference with the processes of normal keratinization. This phenomenon of dyskeratosis is particularly apparent at the follicular orifices which are commonly filled up with keratotic plugs of proliferating epithelial cells.

The third commonly associated feature of a hypothyroid skin is dry, lustreless hair and a tendency to alopecia, diffuse in type or local; particularly characteristic is sparseness of the outer third of the eyebrows—*signe de sourcille* of the French. The dermatological syndrome of hypothyroidism is well expressed by this clinical trinity, dryness and harshness of the skin, slight exfoliation and a tendency to alopecia.

HYPOTHYROID DERMATOSES.

Various dermatoses have been tentatively associated with hypothyroidism. Thus, seborrhea is assumed by D. W. Montgomery (4) to have had a hypothyroid basis. I can accept this assumption only half way; only so-called dry seborrhea fits well into a hypothyroid syndrome. The oily seborrhea, clinically and physiologically, is the exact opposite of hypothyroidism. The hyperactivity of sebaceous and sweat glands in oily seborrhea negatives decidedly any possible relationship between it and hypothyroidism, the basic effect of which is the diminution and checking of glandular activity.

On the other hand, dry seborrhea comes clinically close to the hypothyroid skin. In dry seborrhea, normal fatty degeneration of the glandular epithelium and its transformation into oily secretion are interfered with, and proliferation and accumulation

of the epithelial cells, as dry follicular plugs, are observed. From this point of view dry seborrhea should be dissociated from oily seborrhea, as it presents a rather abortive type of it, and would seem to be more properly placed among follicular dyskeratoses.

The clinical conception of kerosis, introduced by Darier (7), seems to be a name well suited to dry seborrhea. Darier's description of it as a syndrome consisting of dirty yellowish and grayish color, the accentuation of pilosebaceous pores and slight thickening of the integument, seems to be also a good description of a hypothyroid skin, even if Darier himself at the time did not interpret it as such.

Ichthyosis has been advanced as a hypothyroid condition, both because in a few cases it has been found as a disease or atrophic condition of the thyroid, and also because of the many favorable reports in ichthyosis from the administration of thyroid.

Scleroderma has been persistently associated with hypothyroidism by many observers. A certain clinical resemblance between the edematous stage of scleroderma and myxedema cannot be denied. In spite of the fact that pathological findings of the changes in the thyroid in scleroderma are rather conflicting and in spite of the fact that therapeutic results of thyroid administration are far from being uniform, the thyroid treatment in scleroderma seems to be strongly indicated, as we have nothing better or more promising, neither in the way of therapeutics nor in the way of a theoretical explanation of the condition.

CLINICAL INDICATIONS OF THE THYROID THERAPY.

On the strength of the skin changes observed in hypothyroid cases, the clinical indications of thyroid therapy in skin diseases can be drawn fairly definitely. As a general indication, dry, harsh, slightly thickened and scaly skin, with itching or without, unless explained on some other specific grounds, calls for thyroid treatment. Various clinical forms of hyperkeratosis and dyskeratosis justify a tentative thyroid medication. Here belong ichthyosis, hereditary plantar and palmar keratosis, lichen pilaris and Darier's follicular dyskeratosis. It is a clinically established and generally accepted fact that many cases of dry chronic papulosquamous eczema benefit by the administration of thyroid. It is immaterial whether we assume that these types of eczema are etiologically related to hypothyroidism, or, having a different etiology, simply happen to be in a hypothyroid individual, and therefore benefit from the thyroid indirectly. The fact remains that a large number of these cases clear up under thyroid therapy where nothing else helps. In my opinion these cases are not uncommon, and their number will greatly increase as the clinicians become better acquainted with the fact of their existence.

It has been also reported by a number of clinicians that certain cases of psoriasis improve under thyroid administration. In my opinion such cases are by far not as common as hypothyroid eczema. Great caution should be used in selecting cases of psoriasis for thyroid therapy; only sluggish, dry, and chronic cases should be taken. Cases that show a tendency toward an acute inflammatory course and profuse desquamation are not suitable.

There is one class of cases eminently suited for thyroid medication, that is prurigo of Hebra's type and its abortive or incomplete forms occurring ordinarily as chronic urticarias in children—so-called strophulus. I believe that prurigo, as described by Hebra, is nothing but a dermatological syndrome of a severe degree of hypothyroidism. Its clinical picture comprises every feature of hypothyroid skin, barring its extreme manifestation—myxedematous degeneration. The skin in prurigo is dry, harsh, thickened and rough, particularly on the external surfaces, with a faint branny exfoliation and the sweat glandular function checked or suspended. Seasonal aggravation in winter and a tendency toward dry papular eczematization are also suggestive. The real type of Hebra's prurigo ferox is extremely rare in this country, but its mild and abortive types, chronic papular urticarias of children, are rather common and present a legitimate field for thyroid medication.

I consider senile pruritus as one of the most interesting and promising clinical indications for thyroid medication. It is an empirical axiom that merely oiling senile skin brings relief in senile pruritus, thus indicating that a paramount, if not exclusive, factor of senile pruritus is the lack of natural secretion. Whether the thyroid atrophy in senile pruritus is more marked than that of other endocrine glands, or whether thyroid hypofunction develops as the incidental feature of general physiological decline, is of secondary importance. The fact of clinical interest is that thyroid in small doses acts favorably in senile pruritus. Apparently, different textural elements of the senile skin do not atrophy in all cases at the same rate of speed, as we often see a marked senile atrophy of the skin manifested, thinning, pigmentation, keratoses, secondary venous telangiectases, without itching. In these cases the glandular activity is retained and the skin is not dry, itching is not observed, and thyroid therapy is, obviously, not indicated. Following the same line of reasoning a generalized pruritus associated with a dry, harsh, scurfy skin, which cannot be explained by any specific dyscrasia, such as diabetes or leucemia, should be regarded as potentially hypothyroid and given thyroid medication.

OTHER ENDOCRINES AS THERAPEUTIC AGENTS.

As mentioned above, the hypothyroid dermatoses present the most tangible and specific relationship and for this reason offer the most definite therapeutic results. The clinical utilization of other endocrines is resting as yet on speculative and conjectural bases. Yet, with the extension of research in this new field, the clinical and experimental facts underlying these therapeutic attempts are getting more numerous and steadily gaining in significance. Thus on the strength of the well established clinical observation that ovarian dysfunction aggravates, if not produces, acne vulgaris, rosacea, urticarias and various vasomotor skin symptoms and paresthesias, ovarian therapy is perfectly justifiable and indicated in these conditions. Symptomatic relief of urticaria and angioneurotic edema by adrenalin is well known. Favorable hemostatic action of pituitary posterior lobe on purpuric conditions is also clinically demonstrable.

The use of the digestive hormones in various dermatoses, due to the wrong assimilation and to intestinal toxemia, seems plausible and well indicated. The adrenal glands are reported occasionally beneficial in vitiligo and are worth trying, since there is no more rational or more promising therapy of the condition available.

RELATIONSHIP OF THE ENDOCRINOTHERAPY TO THE LOCAL DERMATOLOGICAL TREATMENT.

It is of the greatest clinical importance to have a clear conception of what can be expected from endocrinotherapy in skin diseases. Endocrinotherapy is a constitutional treatment affecting skin lesions through the direct or indirect influence of the trophic nerves and through a stimulation or depression of various structural elements of the skin. Its possibilities and limitations are determined by peculiarities and distinctive features of the cutaneous pathology. These peculiarities constitute a keynote to the problem of the therapeutic control of skin diseases.

PECULIARITIES OF THE CUTANEOUS PATHOLOGY.

All that any constitutional method of treatment, including endocrinology, can do and should be expected to do, is to prevent a recurrence of new skin lesions by eliminating, correcting or neutralizing the systemic pathogenic agent. It may and often does facilitate the clearing up of the present skin lesions by removing the source of cutaneous toxins and irritants. But it should be made definitely clear that systemic treatment is not sufficient to clear up local skin lesions without local treatment. The reason for this is that of all the organs of the body the skin is the only one which has a peculiar topographical location on the surface, rendering it subject to a constant irritation from all kinds of irritants—biological, mechanical, physical or chemical, endogenous or exogenous, and last but not the least, that specific dermatological insult, scratching, due to intolerable itching. Because of this, skin lesions, even if originally caused solely by a systemic irritant, develop a chain of secondary pathological changes, such as eczematization, lichenification, staphylococcus and streptococcus infection. These secondary local changes develop and perpetuate the inflammatory process independently of the systemic etiology, and cannot be controlled by the systemic etiological treatment of the primary cause, because their development has been determined by the local etiological factors. Only appropriate local treatment, applied simultaneously with the systemic, can break the vicious circle of pathogenic factors, systemic and local, intertwined and mutually retroactive in these conditions. This is why local treatment is indispensable in all types of dermatoses, both systemic and local, and why the best results in systemic dermatoses are obtained by the combined treatment, systemic and local.

On the strength of this clinical observation, in all cases I have combined endocrinotherapy with the appropriate local treatment. The assumption that the local treatment detracts from the validity of the claims of endocrinotherapy is easily refuted, not only by the fact that the administration of endocrines prevents the recurrence of skin lesions, but also by the fact that the addition of endocrines to

local treatment clears the lesions where local treatment alone was ineffective.

CASE REPORTS.

The following cases have been selected from a large number, and are cited merely to illustrate the clinical type where favorable results from endocrinotherapy, preeminently the thyroid, can be expected:

CASE I.—Mrs. A. L., aged twenty-seven, married; a frail, highly neurotic woman who had suffered from a distressingly itchy, dry, papular, recurrent eczema of the chest, back and upper limbs for eight years. Local treatment, including x ray, had given only a short relief. Food proteid tests for beef, pork, eggs, etc., were negative. Various restricted diets were ineffective. Dry skin had suggested hypothyroidism as a possible underlying condition, and thyroid tablets were given. The patient improved and remained free from the attacks.

CASE III.—A. F., male, aged sixty-five, came with a patch of lichen simplex on the back of the neck. He also complained of an itchy, uncomfortably chilly feeling all over the body, and of sleeping badly. The local applications improved the patch of lichen, but had no effect on the generalized pruritus. The dry, chappy and slightly exfoliating condition of the skin all over the body suggested a possibility of hypothyroidism. The administration of one grain thyroid tablets brought about lasting relief from the general pruritus, the improvement in the condition of the skin, and still more markedly in the general feeling.

CASE IV.—Miss L. P., aged eighteen, came with a severe case of alopecia seborrhœica of the scalp, a condition which had been slowly developing from early childhood. The seborrhea was of a marked, dry type, with the sebaceous plugs filling up the follicles. The skin of the whole body was dry, scurfy, and presented on the extensor surfaces widely distributed lesions of lichen pilaris. The patient was complaining of chilliness, weakness and general malaise. Hypothyroidism was suspected. Under pluriglandular medication and local treatment, not only the local condition but also the texture and nutrition of the skin of the whole body, as well as the general condition, steadily and markedly improved. After one year of treatment and medication, alopecia of the scalp and the general bodily condition showed a striking improvement.

CASE V.—L. P., male, aged ten, inmate of an orphan asylum, undersized, dwarfed physically, with a senile look, came with a disseminated ringworm of the scalp. After x ray epilation the ringworm lesions cleared up, but the hair came in very slowly, in some parts sparse and decidedly grayish, instead of the original black color. In a search for the cause of malnutrition a general examination of the body was made. A mild degree of ichthyosis on the dorsal surfaces of the hands and knees was found, also numerous lesions of lichen pilaris on the arms and thighs. The whole skin was dry, chappy, slightly thickened, and faintly desquamating. Hypothyroidism was reasonably certain, and hypopituitarism was suggested by the retarded growth. Under pluriglandular medication, combined with local treatment, the skin and general condition showed a slow but steady improvement.

CASE VI.—Mrs. N. S., aged thirty-six, married, gravida in sixth month, complained of an intolerable generalized itching of a few weeks' duration. Two months previously she had had influenza. The examination showed numerous dry, discrete, non-inflammatory papules scattered over the trunk and the limbs with a predominance on the extensor surfaces. Clinically, the case impressed one as a papular form of dermatitis herpetiformis, or one of the toxic dermatoses of pregnancy. However, the unusually dry skin and the statement volunteered by the patient that she had difficulty in perspiring, suggested a possibility of hypothyroidism as the underlying factor of the skin condition. Thyroid tablets, one grain each, three times a day, together with the local application of liquor carbonis detergens, had a striking effect. The pruritus cleared up in two weeks, and the patient has remained well.

CASES VII and VIII.—A girl of ten and a boy of twelve, cases identical in type and similar in distribution. Both had dry papular eczematous patches on the face, the girl for eight years and the boy for five years, practically without changes or remissions. The girl had also had numerous large papules, suggesting prurigo somewhat, mainly on the extensor surfaces of the limbs. The features, unlike an ordinary eczema, were the persistently dry and stationary character of the patches, and their discrete type and lack of tendency to run together and form diffuse ill defined areas. The boy also had a perceptible thinning out of the outer third of the eyebrows. Both patients improved greatly on the combined treatment of thyroid and local application, while the local treatment alone had only slight and temporary effect.

CASE XI.—L. M., male, aged sixty-three, came to the clinic, complaining of itching all over the body for the past several months. Inspection showed the whole body, including the head, covered with scratch marks and excoriations, partially suggesting scabies or pediculosis, and still more the combination of both these conditions. A possibility of senile pruritus was rejected, as the skin did not present any atrophic changes. Then two pediculi were observed walking on the back of the patient, and this misled me into the adoption of the first provisional diagnosis—pediculosis corporis combined with scabies. However, the routine antiparasitic applications had no effect, and for two months the patient showed practically no improvement. Atypical dermatitis herpetiformis was then considered, but Fowler's solution gave no results. In search for a diagnosis the patient was reexamined, and two symptoms were detected which threw an entirely new light on the case: first, dull and sluggish mentality, and stolid, slightly puffed up habitus of the patient; second, a marked alopecia of the outer third of the eyebrows. Hypothyroidism was strongly suspected, and thyroid tablets given. A marked and steady improvement at once set in. Three months later the patient looked better than at any time since the beginning of the observation. This is an interesting case, showing how easily one may be misled by a false clue in diagnosis.

ENDOCRINOTHERAPY VERSUS OTHER METHODS OF TREATMENT.

The final estimation of the relative value of endodermatology cannot at this early stage of its development be attempted even tentatively. However, its general position can be stated even now. Various methods of systemic control of dermatoses in use at present, such as vaccines, anaphylaxis food tests, autogenous serum injections, nonspecific proteid treatment, are all based either on a hypothesis or a deductive principle of a purely speculative nature, or, at the best, are resting on the concrete foundation of a few empirical observations from which a deductive theoretical principle has been evolved. Unfortunately, not one of these methods has proved uniformly successful. A principle demonstrated by the basic empirical observation could not be successfully applied on many clinical phenomena apparently of identical nature. This has been the main stumbling block and the main limitation of these methods, yet they are accepted as being legitimate and of sufficient scientific accuracy for clinical purposes. Endocrinology offers as much, at least. Its deductive principles are built on a rock bottom foundation of empirical observation. The basic endocrinous dermatological syndromes of myxedema, hyperthyroid skin, Addison's bronzelike dyschromia, acromegalia and adiposogenital dystrophia, are as concrete, definite and conclusive as any used in clinical medicine as the bases for therapeutic utilization. The system of theoretical hypothesis and clinical research built up on the foundation of empirical data is as fascinating, comprehensive and plausible as any of the scientific hypotheses and methods used in clinical research. This being so, I firmly believe that endocrinology should be incorporated into the dermatological armamentarium as a scientifically valid method of great clinical efficiency, even at this early stage of its development, and of unlimited therapeutic possibilities in the future.

SUMMARY.

In the final analysis of the clinical and theoretical data presented, the following deductions seem to be justified:

1. Endocrinotherapy can be accepted as the method scientifically valid and clinically effective.
2. Hypothyroid dermatoses are the most definitely established and therapeutically successful group.
3. To the hypothyroid group can be assigned, apparently, the following dermatoses: a. Various forms of dyskeratosis: ichthyosis, congenital keratodermias, Darier's kerosis, lichen pilaris, Darier's keratosis follicularis. b. Certain dry squamous eczemas and certain cases of psoriasis, Hebra's prurigo, senile pruritus and hypothyroid pruritus, possibly scleroderma.
4. Indirectly and nonspecifically various hormones are beneficial in various symptomatic dermatoses, such as acne vulgaris, rosacea, dietetic and vasomotor dermatoses, and diabetic eczemas.
5. The substitution principle of endocrinotherapy, i. e., the supply of deficient or absent hormones, at present is the most productive and clinically most applicable.
6. The best results are obtained by the administration of small doses for a prolonged period of time.

BASAL ENDOCRINE THERAPY.

By JOHN J. McNULTY, M. D.,
New York.

"His (Galen) keen appreciation of the unity of the organism, and of the interdependence of its parts; his realization that the vital phenomena (physiological and pathological) in a living organism can only be understood when considered in relation to the environment of that organization or part. What Galen combated was the tendency, familiar enough in our own day, to reduce medicine to the science of finding a label for each patient, and then treating not the patient, but the label. . . . the dangers which would beset the medical art if it were allowed to fall into the hands of a mere crowd of competing specialists without any organizing head to guide them."—A. J. Brock's *Galen*, 1916.

This, it seems, is the present danger from a "mere crowd of competing specialists." Endocrinology and endocrine therapy is dangerously beset, at present, with self-labeled endocrine specialists who are placing an atmosphere of vaudeville over this recently revealed domain of research—a domain that is not only new but has possibilities of demonstrating a new and greater service to the diseased.

"Not only do animals know the food that will suit them best, but they find out the most suitable remedies when they are ill, and constantly form a correct diagnosis of their malady with a therapeutic knowledge which they cannot possibly have acquired."—Butler's translation from Van Hartman.

Basal endocrine therapy, to be the employment of present day means to help the disordered or diseased, must consider basically the organism not only as a whole but in its relation to environment. To recur to our thematic note—the organism in perspective—biological perspective; and biological perspective includes and is dependent upon environment to give true values.

We seem to be coming into a recognition of an unconscious knowledge which is more knowing than our conscious deliberation, and upon this unfolding and higher sense of truth and law, we shall find a higher, truer, and more serviceable therapy. We shall depend upon organic selection instead of gratuitous interference—gratuitous interference which summarizes much of our present ignorant therapy. Unconscious knowledge is the perfect law of internal environment in its play with self and its interplay with external environment—psychophysical man and his environment. In our ignorance we have been interfering too much. Let us alertly observe, and alertly cooperate, but not interfere. Basal endocrine therapy is based on a working degree of consciousness—biological consciousness—a consciousness that has a sense of values and does not confuse the part with the whole. Our present sense of endocrine therapy seems only an expression of partial knowledge of values and relations. That which some modern psychologists call unconsciousness is, in reality, intimations of the only consciousness; that is, unconscious knowledge. Working forms of thought, such as classical endocrine syndromes, are serviceable if placed in their proper relation to the whole—the biological whole, so far as understood.

To us the error, and the danger, of holding to fixed concepts—classical endocrine syndromes—is that the fixed concept is not the fact in the condition—that the obvious is not necessarily the actual cause of the morbid phenomenon. The fixed classical endocrine syndrome called Graves's disease is not necessarily a primary thyroid disorder or disease. The gratuitous—and generally inaccurate—differential classifications of the organism's imbalance into such terms as Graves's disease, myxedema, acromegaly, Addison's disease, are not only gratuitous but inaccurate if treated with this partial concept.

Those obsessed with a desire to create and establish a fixed, definite differential endocrine pathology will sooner or later find themselves bewildered and enmeshed in their own weaving. Endocrinology and endocrine therapy can become logical and serviceable only to the degree that the so-called practicing endocrinologist holds clearly the biological concept of the unity of structure and unity of function in man (organism) as a functioning whole.

Therapeutically considered there are no endocrines—the endocrines are the endocrine—automatically reacting (unconscious knowledge) as an interrelated and interdependent, organic regulation—internal environment reacting with external environment. Classical endocrine syndromes are quite all right if we understand the partialness of the phenomena as guides to helpful diagnosis and therapy, but they are certainly dangerous if accepted and acted on as the whole of the disorder or disease.

"... Many men of the highest eminence are only partially educated." Morley Roberts, 1920. I fear this is true of many of us. When we try to press our partial knowledge into a fixed classical mold and to affirm its perfection and completeness, we seriously err. Plasticity is man's only hope. "A very slight study of the history of science reveals, however, that the problems which are incapable of solution receive it before the ink of the incredulous is dry."

One of the many reasons why classical endocrine syndromes should not be held in the thought of the therapist as a complete or true picture, and treated as such is that "no case can be prejudged from observations made in any other case. Every case is peculiar."

We differ, basically, with those who seek to establish classical endocrine syndromes and a definite meaning to classical endocrine syndromes. We have been, and conspicuously are at present, juggling with words, synthetic terms, vaudeville dramas. Such biological facts as stand revealed are our only guides to diagnosis and treatment of so-called endocrine disorders or diseases.

Classical endocrine syndromes are misleading if we place reliance on them as definitely understood single or partially grouped endocrine gland disorders or diseases. A thyroid imbalance usually indicates an ovarian disturbance as well, and a thyroid and ovarian imbalance indicates an imbalance or disturbance in all the endocrines now supposed to constitute the endocrine cycle—the interrelated and interdependent reactions of the autonomic mechanism—organic regulation—a human organism biologically understood.

Asclepiades "bids us to distrust our senses." This is peculiarly true when classical syndromes ask recognition. Basal endocrine therapy, we affirm, is based on what Galen called "Nature's faculties of attracting what is appropriate." This statement of Galen epitomizes our idea of basal endocrine therapy. It would seem better for society, *en masse*, that present day therapy return to some of the visional understanding of such early Hellenic physicians as Galen.

The modern biological therapist, the helpful therapist, sees more of duty than of technic—more of cause than mere effect. The practical modern endocrine therapist is quite familiar with and quite master of the technic of differentials, but while using his technic he is not hindered, mystified by the obvious alone. Where we have failed is in treating the obvious alone.

Modern endocrine therapy must consider the whole organism—consider internal environment and its reactions with external environment. A practical, simple working concept must be held as to the ever operative law of repair within, and as part of the organism's potential resources. We must work with organic regulation and as organic regulation works. Endocrine therapy, sufficiently understood, is the best means of working with organic regulation and its law of repair and maintenance.

"Merely give Nature a chance and most diseases will cure themselves."—Hippocrates (Fifth century, B. C.). We must look back to the visional utterance of such as Hippocrates, as well as to the man of vision of today, that we may escape the errors of superficial and inaccurate concepts in the treatment of disorders.

No matter whether we wish to or not, we are going to be forced into more rational and successful therapy through the rapidly increasing intelligence of the so-called laity. The people are going to leave us and go to so-called cults, unless we can render better and more permanent results from our therapy.

Writing of Hippocrates, Dr. Brock states: "His (Hippocrates) keen sense of the solidarity (or, rather, of the constant interplay) between organism and its environment." It is this "interplay between organism and its environment" that modern therapists must seriously consider if they would use endocrine therapy helpfully.

Let us consider the unwisdom and the disaster of treating classical endocrine syndromes as detached, local, and definite and pathological entities.

In viewing organic unity we do not lose sight of the importance of its constituent parts, but desire to call attention to organic unity as a basic concept, and then to consider, in their proper relation, constituent parts. This is particularly applicable to our thought concerning clinical endocrine syndromes.

Classical endocrine syndromes are to us but "the tyranny of names." They form too definite concepts to be accurate, and too definite a therapy to be curative. Endocrine syndromes, as we have stated before in this article, are not entities but complexes that are read differently by different observers.

We would like to quote here Arthur John Brock, M. D., of Edinburgh, 1916: ". . . We are all acquainted with the medical man to whom a name

(such as, let us say, 'tuberculosis,' 'gout,' or 'intestinal auto-intoxication') stands for an entity, one and indivisible, to be treated by a definite and unvarying formula."

We have been taking the stand, with clear confidence, that there are no such entities as tuberculosis, rheumatism, etc., *ad infinitum*, but that these so-called entities are but objective radicals of a basic disturbance of metabolism—an imbalance of the entire endocrine cycle functioning.

"What, now, is this 'Nature' or biological principle . . . which . . . is constantly overlooked—if indeed ever properly apprehended—by many physiologists of the present day? By using this term Galen must imply that, when we deal with a living thing, we are dealing primarily with a unity, which, *quâ* living, is not further divisible; all its parts can only be understood and dealt with as being in relation to this principle of unity. Galen was thus led to criticize with considerable severity many of the medical and surgical specialists of his time, who acted on the assumption (implicit if not explicit) that the whole was merely the sum total of its parts, and that if, in an ailing organism, these parts were treated each in and of itself, the health of the whole organism could in this way be eventually restored."

We are at oneness with Galen in his idea of unity—the organism as a whole—so far, at least, as therapeutical approach to organism is concerned. Our sense of present day endocrine therapy is not its relation to classical endocrine syndromes, but its scientific and demonstrable value in the treatment of basic metabolic errors, which assume varying endocrine syndromes—individual variances from type.

We wish to state here that our belief is that obvious endocrine disorders or diseases indicate involvement of the whole endocrine cycle or mechanism; therefore the logical basic treatment of endocrine disorders or disease is the employment of associated endocrine gland substances—all endocrine substances in biological association—and allowing the only law, the law of organic appropriation, to function; that is, the law of unerring selection—the activity of unconscious knowledge.

"Galen expressed this idea in the unity of the organism by saying that it was governed by a *Physis* or *Nature*, with whose 'faculties' or powers it was the province of *Nature* lore to deal."—Brock. We affirm, with Galen (*vision*) that it is with "Nature lore" that the enlightened therapist deals. We are commencing to catch glimpses of the consciousness of internal environment, internal organism and its every endeavor to express total balance in its total reactions—internal environment reacting to external environment—a phase of "the Immanence of Health."

"The living organism is a creative artist. This feature may be observed typically in its primary functions of growth and nutrition; these are dependent upon the characteristic faculties or powers by virtue of which each part draws to itself what is proper or appropriate to it, and rejects what is foreign, thereafter appropriating or assimilating the attracted material."

This is the whole and basic biological principle

on which associated endocrine substances are given. Nature, or the unerring law of organic selection, knows what to select, and only Nature, organic selection, knows. Selection—organic selection—is this faculty potential. "But the more we learn about the delicacy and complexity of the regulating processes, the more definitely does a difficulty appear."—John Scott Haldane. Let us recognize this "delicacy and complexity" enough not to ignorantly embarrass it with treating it as classical endocrine syndromes.

We are commencing to think in terms of function rather than structure, for an understanding is occurring in us that function, physically considered, is life, and that structure is but an incident of function. It is clear to us that no one is qualified to practise endocrine therapy who has not at least a certain amount of biological understanding of organism as a unified phenomenon or function.

We hope that endocrinology and endocrine therapy will not become a vaudeville, but it will become a vaudeville unless we properly appraise the value of the activities of the vaudevillists—the superficial activities of the superficial. • Biological understanding and biological therapy—scientific endocrine therapy, is here and will abide. As vision comes to earnest and qualified researchists, we all will partake of the reflected light and work in fuller light—a light in which we shall not stigmatize our fellowman with fixed and fatal terms—classical endocrine syndromes.

We are now treating successfully, as intelligent cooperators with the inherent law of repair, conditions we "diagnosed" as hopeless, fatal. This is largely the result of more biological understanding—catching glimpses of how Nature works, and co-working with organic law.

"The researches of the anatomical school of Alexandria had been naturally of the greatest service to surgery, but in medicine they sometimes had a tendency to check progress by diverting attention from the whole to the part."—Brock's Galen, 1916.

"That the best physician is also a philosopher." While this was true in Galen's times, we can now say that the best physician is also a scientific philosopher. Without the urge of scientific philosophers, there would be no real research.

We must use the "Mind's eye as an aid to the physical eye."

We take definite and decided issue with the statement that introduces an article on endocrinology in a recent issue of the NEW YORK MEDICAL JOURNAL, which reads: "Endocrinology is the study of diseased functions, etc., etc." Endocrinology is not the study of diseased functions. It is a study of the phenomenon of health, in which study deviations from the normal are noticed and placed in their right relation to normal function.

It is this obsession to think only in thoughts of disease rather than holding the normal in thought that has been the Nemesis of medicine, and which is driving the so-called laity away from us to so-called cults. The laity are rapidly discrediting the disease-monger.

"Life manifests itself in two ways—as structure and as activity. But we also recognize . . . that

this is living structure and living activity. Each part of the structure bears a more or less definite spatial relation to the other parts, but it is actively maintained in that relation." Between organism and environment a constant active exchange is going on. But this exchange, in so far as it has any physiological significance, is always determined in relation to the rest of the living activity of the organism. "The living body and its physiological environment form an organic whole, the parts of which cannot be understood in separation from one another."—Haldane.

How long will it be before the practical practising physician will understand this basal fact? He certainly cannot be a serviceable therapist until this truth is understood and demonstrated in his clinical work.

17 EAST FORTY-SECOND STREET.

Treatment of Hiccough.—G. Leven (*Presse médicale*, December 29, 1920) recommends lying face down on the floor as a measure for arresting hiccough. In illustration he cites the case of a patient who had had hiccough for three days and in whom a variety of well known remedial procedures had failed. A few minutes after he had been told to lie down face downward he left the office wholly relieved. Frequently it is advisable also to reduce the irritability of the gastric mucous membrane by prescribing two grams of sodium bromide a day in divided doses after meals as well as one tablespoonful every two hours, five or six times a day, of ten grams of bismuth subcarbonate and twenty grams of acacia in 300 mils of sterile distilled water.

Hemostatic Agents.—P. Emile-Weil (*Bulletin de l'Académie de médecine*, March 1, 1921) notes that certain substances, such as emetine, while actually possessed of hemostatic activity, do not appear to act either through vasomotor change or modification of coagulability. Blood serum reduces the delay in the coagulation of hemophilic blood *in vitro*; it acts similarly when injected subcutaneously or intravenously, and at the same time lessens the manifestations of hemophilia. A more important test is that of determination of the bleeding time. The blood flowing from a small incision in the lobe of the ear, when wiped off every thirty seconds, normally continues to exude for three to three and a half minutes. In all chronic hemorrhagic states this bleeding time is increased to from five minutes to two hours. Cases in which the bleeding time is persistently between ten and fifteen minutes are particularly favorable test objects for the study of hemostatic agents. The vasoconstrictor agents such as adrenalin reduce, and the vasodilators such as amyl nitrite increase, the size of the drops which exude, but neither of them alters the bleeding time. Coagulant agents, on the other hand, produce a definite effect on the bleeding time, some immediately and in a lasting manner, like pituitrin, others more slowly, including blood serum and human blood injected under the skin or administered by transfusion. Emetine, while seemingly acting neither on the vessels nor on coagulability, likewise reduces the bleeding time; hence its use is justified. Studies of the blood platelets are greatly to be desired.

Collectanea

Flies as Distributors of Intestinal Protozoa.—Since the classic positive demonstration by Smith and Kilbourne that insects may be instrumental in the transmission of disease, the house fly has often been accused of being one of the disseminating agents (*Journal A. M. A.*, June 4, 1921). Today this familiar insect pest stands not only accused but also repeatedly and convincingly convicted of the serious charge. The association of the fly with pathogenic bacteria is frequently pernicious to public health. The microorganisms of suppuration, the germs of typhoid, cholera, dysentery and tuberculosis, not to mention others less prominent in the public mind, have been detected in league with this omnipresent insect traveler. The incrimination that epidemics may be brought about through the dissemination of infectious material by flies has repeatedly been sustained. How persistently they may harbor the sources of danger is shown, for example, by Ficker's observation that flies fed on typhoid cultures may still give off the bacilli twenty-three days after infection. Heretofore the bacterial parasites have claimed foremost consideration in relation to the fly. But now a new menace looms up. Root, an entomologist of the newly established School of Hygiene and Public Health at Johns Hopkins University, has demonstrated the possibility of a hygienically undesirable association between flies and intestinal protozoa, including the genus *Endameba* of unsavory reputation. Fortunately, the free forms ingested by flies are apparently killed within an hour without encysting. But cysts of the intestinal protozoa survive much longer in the bodies of flies. According to Root, flies feeding on a human stool containing cysts or free forms of intestinal protozoa

will take large numbers of them into their intestines and deposit them again in their own feces. Since all stages of the protozoa are killed within a few minutes by drying, such fly feces are dangerous to human beings only when deposited on moist or liquid foods. A fly which has once ingested fecal material containing protozoa may deposit feces of its own which contain the infective forms of the protozoa at any time from a few minutes after feeding until the most resistant forms, the cysts, are dead. The deposited cysts of amebas may survive as long as two days under favorable conditions. These experiments emphasize anew the importance of flies as carriers of disease producing organisms from human feces to human food.

The Significance of the Bacteria Found in the Throats of Healthy People.—Arthur J. Bloomfield (*Bulletin of the Johns Hopkins Hospital*, February, 1921) made frequent cultures of six healthy individuals' throats, covering a period of from one to three months. The organisms present were divided into two groups, the true normal flora including nonhemolytic streptococci and gram negative cocci, and pathogenic or nonpathogenic organisms which are accidentally introduced and are present usually only a short time in a given individual.

Scepticism as a Freudian Defense in Reaction. **A Psychoanalysis of Bazaroff, the Hero of Turgenev's Novel, Fathers and Sons.**—Jackson Edmund Towne (*The Psychoanalytic Review*, Vol. VII, No. 2, 1920) shows how truly Turgenev has analyzed the neurotic Oedipus complex in a son in this fictional character. He shows the typical irritated, antagonistic attitude toward the superstitiously credulous mother, which is an indirect and overcompensating result of the unconscious fixation. His complex leads him to become the nihilist and to manifest indifference and positive contempt toward his parents. He gives evidence also in love and in his conscious memories of childhood that his libido is checked or warped by some fixed neurotic attitude, though his defense forbids any keen consciousness of what his childhood memories associated with this were.

Is Sprue Endemic in the South?—Mark F. Boyd (*Southern Medical Journal*, April, 1920) believes that the evidence advanced by Ashford that the specific yeastlike organism, *Monilia psilosis*, is the cause of sprue appears conclusive. Manifestations suggestive of sprue may be observed in persons who have never been outside the United States, and from these persons Ashford's monilia may be recovered. Sprue, by reason of the disability it produces in the tropics, is of distinct public health importance. Its importance in the southern United States is as yet undetermined. Potentially it may equal hookworm disease or pellagra, so every effort should be made to ascertain its incidence and present its characteristics to southern physicians. Our knowledge of its means of transmission is nil, but from the situation in which the organism can be demonstrated, it would appear that measures designed to reduce contact and promote proper disposal of excreta might be of value in its control.

Modern Commentaries on Hippocrates*

The Humoral Theory and Its Application

By JONATHAN WRIGHT, M. D.,
Pleasantville, N. Y.

The difficulty the modern essayist has in commenting on the writings of the ancients may not always be due to their obscurity. I realize, as I engage in it, the force of the hint Goethe threw out to his critics, that possibly the light burns dimly with me. Miss Miliona started a thrift class when she heard her father, the steel magnate, say what we needed was more labor and less bread. When we wanted peace a master of motors chartered a ship and went after it. When a foundryman and a politician entered literature, they started in to reform the English language. When a weaver found his purse fuller than his time, he began to show the farmer how to milk his cows and plant his potatoes. When a doctor devoted to mortality statistics got the chance he wrote an essay on immortality. There ought to be a field, free for all, reserved for the aberrant industry class in the world's exposition, but even this should be entered by the dry goods expert, interested in artistic architecture, or the soap boiler devoting his last years to poetry, hat in hand and with moveable joints in their spines, characters not acquired by men accustomed to the adulations extracted from a world grovelling at the feet of material success in life. Attempting to keep full in view certain lessons to be garnered from the later life of more distinguished men, when a medical man, though in no way handicapped by materialistic laurels but no longer even politely referred to as middleaged, enters the field of historical criticism, he should first look carefully around him and see who is occupying it and commune with himself as to whether he belongs there. In their new activities it has not been observed that the gilded girl or the foundryman or the politician or the weaver or many another took these precautions, deeming success a matter of course in any of their undertakings. At least he need not add unnecessarily to the gaiety of his own critics by a blindness which seems usually really to arise as much from an insufficient sense of humor as from the acquired characteristics

of persons having attained eminence in fields they have cultivated in earlier years.

All of which admonishes me I have reason to be cautious in differing a little in sentiment from that which one sometimes notices in literature old and new, to the effect that the modern student of the history of medicine, much less the casual reader, can not enter profitably into the field devoted two thousand years ago to the husbandry of philosophy and medical science. I presume from the viewpoint which some critics hold there is a modicum of truth in this. I think it very likely impossible for any one, however studious and however well equipped otherwise, ever completely to grasp or thoroughly to enter into the manner of thought of the ancients, or for that matter into the atmosphere of thought pervading epochs less remote than the term, ancient philosophy, connotes. It is certain one can never be sure that one has really penetrated the inmost recesses of the ancient mind, however assiduous one's study of it. These things may be freely granted. At least it is as impossible to deny them as to prove them. I humbly question, however, whether this is the only viewpoint from which a survey can profitably be made of the beginnings of the history of science. All history, it is said, must be written anew for each generation and the force of the remark is obvious. Each generation taking up its own angle of incident vision and seeking only the lessons it thinks important in history necessitates a continual shifting of the facts in and out of the limelight. That this usually results in the abolition or rather oblivion to the appreciation of the way they were presented to former generations also has its interest for us.

In so far as historians, skilled in the art, make a pretence of furnishing eternal, snow white truth, without fleck or blemish, to a properly obsequious and receptive world, eager for the news from the inmost Olympian circles, I suppose we must acknowledge that such sentiments are correct, but I doubt very much if all the terms of this high ideal are tenable, as sometime expressed. One naturally

*I have used the translations of Adams into English and the French translation of Littré for Hippocrates and Kühn's edition of Galen.

falls into this attitude, when one is too deeply imbued with the self-consciousness of modern science from a wide acquaintance with its literature. I read only yesterday the approving citation of a reviewer, who yielded, coyly perhaps but with graceful readiness, to the bold assertion of an author, whoever he was, that it was false modesty not to assert that all the secrets of nature had been revealed in the processes of a certain disease, or was it some other repositories of Nature's mysteries? It is not well to be too specific about author or reviewer. I only wish to illustrate how easy it is for these gentlemen, for all of us indeed, who linger on the outskirts of things, to absorb some of this spirit in the study of modern medical literature. But is there not something, is there not some grateful thought we can derive from only a proximity to this luminosity of our times without unfortunately encountering its full glare? Is indeed after all the impression general in science, even in medicine, that we know it all? Are there not some at least who are grateful for half truths? These questions are natural in this connection and for me at least are all important.

VALUE OF ANCIENT THOUGHT.

If these are considerations to ponder as to the historians' audience, there are parallel ones not less important as to his work. Even if it is true, and I believe it is true, that it is quite impossible to fathom all the depths of ancient thought, can we not get flashes and gleams of hidden meanings, of meanings at least for us even though false interpretations, that will act as a stimulation to modern thought? Was it Browning or some other cryptic philosopher who, asked what he meant by such a line, answered complacently he was blessed if he knew what he did mean. It was of no consequence. The important thing was to know what it meant to the reader, if anything. It is not of prime importance for us to know what Shakespeare or Homer, Heraclitus or Hippocrates really meant by some cryptic line. What is there in it for us? From Aristotle and Plato we can not hope to derive what it was possible for their contemporaries to learn, nor what the next generation gathered, nor the next and so on for sixty or seventy generations, but it has meant something to them all and be sure it can mean something to us. Otherwise the good they did would lie buried with their bones, but we may equally be sure it was not absolute truth even at the start, not such as modesty can be too modest in concealing. And this abnegation of absolute truth which we make in the face of history, the continual revival of interest from a new angle, this gain of a new point of view from which to behold the panorama and speculate as to its interpretation, has in fact been, with no attainment as yet of absolute truth, an ever ready source of charm and interest for thoughtful men throughout the ages. Without this eternal resurrection, without this new point of view, we should care no more for history than we do for a catalogue of the stars. New ones are discovered, of course, but they have no interest for the public. This can hardly be otherwise in the history of science for scientific men in general. Continually exhibiting new facets of absorbing interest

to the intelligence of the modern worker as he meets facts in his own work new to him, the critical survey of the past, with its incidental reminder that there were brave men before Agamemnon and wise men before Solon, can not fail to be to him a subject of interest and profit, if he will heed. Those gleams of light we get from it may not be such as they existed for former generations. They may not be such as will shine in the future, but this does not wholly destroy the value they have for the present, differing in each it may be and even always wide of absolute truth, if any one knows what that is.

So long as we make no pretence, then, of farming or of reforming the English language, no promise to bring peace to a world in arms, no threat of printing posters to enlighten the poor as to thrift, in so far as we take care not to raise hopes in our readers, which are bound to disappoint, so long as we patiently and cautiously keep hidden the conviction that we possess the well springs of eternal truth, so long as we humbly, manuscript in hand and with many reverences, bow to the editor, who is the best judge what it is practicable, even what it is best for his multitude of urgently exigent readers to read, I think we can still sleep o' nights even in proximity to our neighbor exulting in the possession of everlasting truth. I for one feel that I don't need to worry about it, it being no possession of mine. I am content to leave it to those who rejoice in it. I am content with the impression ancient literature makes on me and if I try to hand it on, such as it is, soiled as it is with my own sordid grasp of it, and the editor gives me a chance, why should I stay my hand because I know it will all be dust and ashes, while the works of genius are immortal? It was not the dream in the old temple slumbers that mattered, it was the interpretation the artful priest of Aesculapius put on it that decided the therapy the patient adopted. This is the sordid grasp to which I refer, having here particularly in mind somewhat I confess the peril of introducing too much of the personal element in formulating the general principles of the humoral theory, which was the subject of the last essay in this journal. It is desirable in the exposition of a theory which had such far reaching effects on the course of the evolution of medicine, not to be content with this personal interpretation but to illustrate it amply at its inception and in its first developments.

TEMPERATURE CHANGES.

Having referred particularly to Hippocrates's great appreciation of season, climate and weather upon man in general outline, it remains to point out the specific manifestations of his convictions in the genuine books of the Hippocratic Corpus. Naturally one first turns to the *Airs, Waters and Places*. It opens with a recognition of the influences of temperature changes in a general way on the system and then specifically we find it explaining that there are waters which are of a heating nature, some having a solvent effect on the bowels, being adapted to boiling but some are intractable and dry up the bowels. At once we grope, quite as admitted in my preceding remarks, but we see the association in the mind of Hippocrates of water both with the dry

and the moist state of the bowels and we learn that to some extent the qualities of an agent are determined not by its own physical condition but by the effects it has on the human system so far as it is classified in the humoral theory. This gives us some enlightenment on how it was possible that a theory so incongruous with all we regard as common sense could appeal to such a mind as that of Hippocrates, ever ready to rebel at any violation of it. In the *Ancient Medicine* he thus attacks its special application. Let a man, he says, of a weak constitution "eat wheat such as the threshing floor supplies, raw and unprepared, with raw meat, and let him drink water. . . . He will experience pains, his body will become weak and his bowels deranged and he will not live long. What remedy? Hot? Cold? Or moist or dry?" Not at all, he answers; change his diet. As far as he knew none of these qualities ever existed alone but always mixed with others, whether we consider them, I suppose, from the physical or the therapeutic viewpoint, but he jumps the later limitations of the theory altogether when he says that in pneumonia, there is something beside the hot mixed with it—the bitter, the salt, the acid perhaps.

TISSUE CHANGES.

He refers to waters which generate stone in the bladder, in such a way, we perceive in the *Airs, Waters and Places*, that there is a connecting thread to the thought we meet in connection with water. Our conception of inflammation has become so largely one of tissue structure and tissue change, it has become so much more associated with its varying etiology, we forget it is but a short time since it was almost exclusively a dynamic conception, one almost entirely symptomatic. For the old physicians it was so exclusively. The sensation of heat in the inflammations of the bladder had a literal connotation for the ancients to a degree foreign to us. The burning sensations in the urethra were real heat. In Hippocrates's view the cause of stone in the bladder was indubitably traceable to the water habitually drunk. Stone in the bladder was accompanied by heat. Water, he thus demonstrates, though cold and wet by nature, gives rise to heat. Thus runs the thought apparently. We see at least that water was heating, of a hot nature in connection with the symptoms.

So when "winter is dry and northerly and the spring moist and southerly, the summer will be of a febrile character," ophthalmies and dysenteries will prevail; it is the fever or the burning or the smarting of these generated by the moist spring weather, preceding the advent of summer, which makes them hot. Here we see certain agents, certain elements, the water and the air, working by contraries, but cross purposes are not the rule. Women are referred to, not only as moist and soft, but as having a cold and relaxed belly. It would seem then that some of the idea of the warm we found connected with inflammations is also inherent in the figure of speech as to sexual appetite, the men being more ardent and hence warm by temperament, the women colder. "The dysenteries are also likely to occur in women and those of a humid tem-

perament." The lack of musculature, the pliable skin, the substratum of adipose tissue we recognize as lending to the ancient mind the idea of moisture in women and children and those of flabby flesh. Soft clay, moist and cold, unbaked by heat, seems to have been the mental association. Dysenteries and violent diarrheas drain the moisture away in their copious stools and leave the plump figure of yesterday a wasted and shrunken frame. I do not know if modern statistical information or even if the impression of modern clinical experience confirms this idea that the plumpness of women and children or the flabbiness of ill nurtured males predispose to diarrheas and dysenteries. In the latter instance perhaps flabbiness and the diarrheas depend on a common cause of intestinal inefficiency, but I suspect the striking change wrought by summer diarrheas on the plumpness of women and children multiplied the cases in the mind of him recording a long clinical experience from memory without the help of statistics, at least in their modern profusion. At any rate, such things fell to the category of humoral theories. Men of a phlegmatic temperament, that is, those subject to catarrh of the upper air passages, "are like to have dysenteries too," perhaps especially when subject to stomach disorders as they sometimes are. There is trouble though for us about the brain; that like the phlegm which comes from it is cold and wet and the cold and wet of the weather increase it. Thus water or moisture we saw producing heat in stone in the bladder, working by contraries, here in the head works by similars. These two principles were as great a blessing to the ancient pedant as the ubiquity of bacteria is to his modern successor.

Why the phlegm is cold we perceive fairly well. Of the body fluids whose physical attributes, when they come under the notice of the observer, are likely to be associated with certain definite mental impressions it is the phlegm which most often leaves the impression of being cold and wet. The blood and the bile are warm when voided, while the phlegm, for long lying in the air passages before coming in contact with the skin of the examiner, is cold. Thus "some have catarrhs beginning in the head and descending to the lungs." It is the cold and wet phlegm for the ancient that caused lung trouble—and we don't form quite so coherent an etiological chain as this now, though we see the gaps in the old one.

CHANGES WITH AGE.

"Those are bilious who have dry ophthalmies from the heat and dryness of the flesh." The thought stands forth when it is at once mentioned in sequence that dryness and hardness of the flesh is connected with old age, for that is dry and hard too, if not hot; "the aged too have catarrhs from the flabbiness and melting of the veins." The cold and wet not seeming to fit in very well with the dryness of old age, there seems a faltering here, flabbiness also not being, it would seem, exactly consonant with the hardness of old age. In fact it is permissible to conclude that sometimes, at least, when we grope, there is an irreconcilable clash which no logic, ancient or modern, no diligence of

search along the mental track, entirely silences. It is a way theories have sometimes even in the best regulated eras, like our own, but it is unsafe, living in an era unsympathetic and intolerant of any logic but its own, to yield too readily to this facile interpretation.

The indications of the correlation of the humoral states of the body with the climate of different countries, of course around the Mediterranean for the most part, are too diffuse to lend themselves readily to citation, but permit the summary that the question of health and disease is inextricably involved in the interrelation of the qualities of the animal system with the characteristics of the weather and the seasons, of water and earth, in the terms of the humoral ideas prevailing in the genuine books of Hippocrates, but often as to the humors themselves this is not specifically avowed, even in this book of the *Airs, Waters and Places*. In the *Regimen in Acute Disease* we scarcely get a glimpse even of these ideas. Still less, if possible do we get any intimation of the qualities in the *I* and *III Epidemics*. In none of the foregoing is there any talk of the discrimination of the body fluids or any reference to the four humors as an exclusive class, etiologically or pathologically, but in the *Epidemics* there is frequent reference to the weather, the climate, and the location in consonance with the treatise we have had chiefly under consideration. Indeed the *III Epidemics* is divided into "constitutions" in which the chief etiological factors are these precisely and only secondarily the humors at all. The *Aphorisms*, some of which may have been independently composed by Hippocrates, some of which selected by him or by others from his genuine works, but some of them too silly and tautological to have been composed by anybody but a fool, exhibit many instances of the frank avowal of humoral doctrines. These are chiefly selections from the spurious books we have not yet paused to consider and therefore there is no reason for supposing the aphorisms, not traceable to either the genuine or the spurious books, are also from the hand of Hippocrates himself. In the *Prognostics* the best emesis is referred to as that which is formed of phlegm and bile, thoroughly mixed and much of the prognosis in pneumonia seems based on this state of expectoration, the yellow color of the sputum being thought of as derived from the yellow bile.

THEORY OF THE COCTION.

The acceptance of the importance of the coction, that is the process whereby the excretions of the air and food passages become loose and are easily voided, corresponding frequently with the crisis in pneumonia for instance, is an acceptance if not of the theory at least of a participation in the manner of thought of the humoralists. In the *Régime in Acute Disease* it is said: "Fasting itself sometimes attracts raw bilious humors to the head and the thorax and interferes with the coction by causing sleeplessness." Further along in this book we find the clue to the theory of the coction in its assimilation with digestion of food and drink, the lack of which also gives rise to insomnia.

In the *I Epidemics* in a persisting ophthalmia the

humor (of the discharge, I suppose, remaining ichorous) continued without decoction. And there were bilious diarrheas, "abundant, irritating, without decoction," sometimes even watery, and again we get the assimilation with digestive processes—but in everything pertaining to the disease there was much humidity, there was vomiting of phlegm and bile and food was returned from the stomach undigested. This coction of the humors is so intimately associated with the theory of crises and critical days, it is difficult to go thoroughly into the matter without going further than my remaining space allows.

There is reason for the remark that the chief internal etiological factors in the process of disease for Hippocrates are the bile and the phlegm, but especially the bile, as that occurs more persistently in the discourse than the phlegm. Littré draws attention to the fact that both the older philosopher Anaxagoras and the younger dramatist Aristophanes allude to the bile as the origin of disease, but Plato still younger, in the *Timæus*, which is supposed to have been written in his old age, probably long after the death of Hippocrates (or in his extreme senescence if we must accept the legends of his longevity) explicitly refers to the four humors as the causes of disease, when their equilibrium is upset by the predominance of one or the other. This matter has been alluded to in the previous paper and while the evidence as to the conclusions reached do not entirely conform to those demanded by the orthodox tenets of science, they are fairly within the usual limits of historical criticism.

It is of some significance in approaching the consideration of the full blossomed humoral theory, such as appears in some of the spurious books of the Hippocratic Corpus and such as Galen handed down to posterity, to note a few special indications which point to its origin in the Sicilian School. This also has been touched upon in the previous paper. From Sicily direct rather than indirectly from the Hippocratic Corpus we may imagine Plato derived his fuller developed humoral theories. In one of the fragments of Empedocles we find the declaration, often quoted by Galen, that the vine draws its characters from the soil. The fourth book of *Maladies* Littré places in a special class (VI) as continuous with several others all coming from some able follower of Hippocrates, before the time of Aristotle; Polybus, Galen thinks, perhaps. This brings it close to the date that I have alluded to for the *Nature of Man*, but from internal evidence, from a significant difference in the treatment of the humors, we infer it certainly is not from the same hand. The author of *IV Maladies* remarks how different are the lands lying around the Mediterranean in the virtues they impart to the vine. This took place, he seems to conceive, by virtue of a power, to which Hippocrates also alludes in *Ancient Medicine*, assimilable to the famed entelechy of Aristotle, so much exploited by Galen in antiquity and also by Driesch and the modern vitalists. The immediate point for us is: "Moreover there are four other sources by means of which each humor arrives at the body—". Those sources

are for the blood—the heart; for the phlegm—the head; for the water—the spleen; for the bile, the part which is in the liver. The food and the drink contain all the biliary, the water, the sanguineous and the phlegmatic elements, some less, some more.” In these origins and organs must exist powers which give them their characteristics. Of course whether it is the neovitalist or this ancient vitalist follower of Empedocles, from whom Aristotle borrowed so much, who begins to discourse on these attractive powers, so convenient for both alike, we advance not a whit, whether we call them entelechy or dynamics. This puerile logic, such as it is, we see disappearing behind Empedocles and the Sicilian school into the mists of the infancy of thought, unrefined by criticism, unfettered by reflection apparently.

In the *Nature of Man* and here also in the *IV Maladies* we find the authors, mindful of what Hippocrates had to say in the *Airs, Waters and Places*, also in difficulties with the details of reconciling all the facts of climate with those of the corporeal system of man. We notice here too the fire that burns the flesh in the humors of an eye afflicted with phlyctenæ and the advice to purge only the concocted humors. We must judge of the medication in disease by the revulsion obtained when the dry becomes warm and the moist becomes cold, for this is the true equilibrium of the qualities. The parable of the vine adopted in the *Nature of Man* runs thus: “What the earth is to trees, the stomach is to animals; it nourishes, warms, refreshes,” and this author runs into absurdities, which neither the author of *IV Maladies* nor, much less, the author of *Airs, Waters and Places* could be guilty of. In *The Humors* as in *The Aliment*, the confusion of language and of ideas often naturally suggests a student with his notebook following a lecturer, steeped in the doctrines of Hippocrates, it is true, but to which, as he dilates on the points in them related to the matter, the teacher adds his own prepossessions for the theory and such interpretations of it as are set forth in *The Nature of Man* and *IV Maladies*. These the note taker in *The Humors* and *The Aliment* sets forth with the usual half lights of the unflashed medical student, foreshortened, abbreviated and confused.

NUTRITION OF THE CHILD.

In the book on *Generation*, which opens the series, with the *Nature of the Child* and the *IV Maladies* following, all of which are supposed by Littré with every appearance of probability to be one treatise by one author, it is declared at the start that the sperm of man comes from everything moist in the body, being the most active part which is thus separated, the essence of the pangeneses of Empedocles(?), of Aristotle at least and of Darwin. Much citation of proof follows, which does not immediately concern us. In the nutrition of the infant in utero nourishment is drawn both from the food which the mother consumes and from the air she breathes. These are attracted, “by the power,” to the child just the same as the stomach absorbs its food, the head drawing to itself phlegm, the liver to itself bile. Here, as in *The Aliment*, air is a

food. Again in the *IV Maladies* we meet with the simile from Empedocles slightly altered. This second reference is to vegetables drawing their particular characteristics each from the soil, their flavor, I suppose. The seed or the grain swells with the air and the humors it draws from the ground. The force (the dynamics) in the humor condenses the most volatile¹ part in the seed. The confusion, I imagine, is in the thought, not in the language alone. Thus condensed by the humor and driven by the pneuma, the seed breaks forth, by virtue of the quality of its dynamics, into leaf and this finds for a while its nourishment from the burst seed itself. The comparison with the child in utero is most excellently worked out, but it is curious to see how the humors and the pneuma play their part in the animal as well as in the vegetable, true to the older pantheistic theory of primitive man, but true also to the terms of the newer humoral doctrine, the warm, the moist, the cold, the dry govern it all.

The text really here takes on an exposition which appeals to us, just as the argument must have appealed to the older Hippocrates, himself too cautious to stretch the theory to the breaking point, a catastrophe, as it appears to us, not avoided by the other authors, carried away by their enthusiasm for the neatness with which it sometimes works, perhaps. It suffices to exhibit how helpful a false theory can be, it is not necessary to show how seductive and misleading it becomes in the hands of those who deliver themselves up to it, typical fanatics in science, spellbound. The parallel reaches its climax when the author triumphantly declares: “Now I return to the purpose which has led me into these explanations. I say all vegetable productions live from the humor of the earth in a state corresponding to the qualities of that humor which the earth contains. So the child lives from its mother in the womb and in a state corresponding to the health of the mother. One may find a perfect similitude between the products of the earth and the product of men.” But his comparison is so successful that his elation leads him astray. He does not heed the wise man’s warning, *pas trop de zèle*. He forces the parable into applications less successful. In parturition the glairy and sanguinolent discharges come from the head, and the source of the blood in general, as today, is a rather complicated process, but evidently the heart and blood-vessels attract it from the food. It is the stomach necessarily that does most of this attracting and we infer the other organs—the head, the heart, the liver and the spleen when the water comes into play—are secondary attractions, the bile, at least in some accounts, being attracted by the liver from the blood. This to us is utter nonsense and chaos. I am not sure an unsympathetic analysis, such as I am making, would not reveal holes in modern physiology, but we will leave that for the amusement of future critics. They will have their share.

¹The hereditary parts of it settled in the seed probably by a sort of pangeneses, since this passage seems to rest on doctrines ascribed to Empedocles, who held them before Darwin and even before Aristotle, apparently. I do not think we can entirely identify “dynamics” with the modern germ plasma, though in this particular passage, the latter modern conception fills the vacancy here, which makes the trouble.

Lung Mapping by the Injection of Bismuth Mixtures in the Living*

By HENRY LOWNDES LYNAH, M. D.,
New York.

Accidental inhalation of bismuth mixtures has occurred at times while patients were attempting to swallow the mixture for a radiographic localization of an esophageal obstruction. Again, bismuth mixtures have trickled through a cancerous tracheoesophageal fistula mapping the bronchial tree (1). In cases of esophageal paralysis the mixture will not enter the esophagus at all, but will be held in the reservoirs of the pyriform sinuses and pour over between the arytenoids into the trachea, and also map out the tracheobronchial tree.

Since the report of Beeler's case, many similar observations have been recorded by such expert radiographers as Gottlieb, Hirsch, Le Wald and Stewart. The bronchial tree has been injected many times in the cadaver, but Jackson was first to recommend the insufflation of dry bismuth powder for localization of small foreign bodies not visible by x ray (2).

Bullock and Gottlieb (3) in an experimental study on animals injected bismuth and barium mixtures into the bronchi and obtained some very beautiful pictures. They were also able to study the action of the bronchi in dogs, and demonstrated a wavelike action in the larger bronchi and trachea.

It occurred to me that bismuth mixtures injected into the lung of the living patient would probably do no harm, especially in those subjects suffering from almost incurable diseases of the bronchi and lungs, such as bronchiectasis and pulmonary abscess; and furthermore, that these areas, which heretofore had never been mapped out, could be definitely localized by the injection of some opaque mixture bronchoscopically which would gravitate into the abscess cavity.

The following patients were injected bronchoscopically with an oily mixture of bismuth subcarbonate.

CASE I.—F. H., a man of twenty-six years, presented a lung abscess in July, 1919, after having aspirated sea water while in swimming. He got out too far and became exhausted and went under. He was hauled out and by first aid measures soon revived. One week later he suffered from what was supposed to be bronchopneumonia and there was much foul expectoration at this time. Within one month the acute symptoms subsided, but he continued to expectorate large quantities of pus. He was sent to New Platz, N. Y., with the diagnosis of pulmonary tuberculosis, even though no tubercle bacilli were found in his sputum. He had fever and also complained of having a bubbling sensation in his right chest. There were severe night sweats at times.

On February 10, 1920, he consulted Dr. F. W. Corwin, of Newark, N. J., who referred him to me for bronchoscopic examination. The radiographic

plates which Dr. Corwin had taken showed a definite shadow over the right lower lobe surrounded by "pus sponge soaked" infiltrated lung. The diaphragm was attached and pulled upward. The radiographer in his report stated that there was a level of fluid and gas bubbles in the abscess cavity. This, however, we were unable to interpret. There was profuse expectoration of foul smelling pus, and the patient stated that he had coughed up as much as would fill a large preserve jar every twenty-four hours, and that he had been measuring the amount of sputum for some time. He was bronchoscoped after a further study of new radiographic plates.

There was a profuse discharge of pus which poured out of the bronchoscopic tube mouth. It was very foul smelling and blood tinged. A seven mm. bronchoscope was introduced so that the lower lobe branches could be studied with ease. After thorough evacuation of the pus filled bronchi, the superior lobe branch on the right side was examined and found on coughing to be free from pus. There was some pus coming out of the middle lobe branch which was directly anterior, but after this branch was sucked out no pus was seen when the patient was instructed to cough. The right lower lobe branches were filled with pus. This was removed by suction and each branch examined in turn and the patient instructed to cough. By this means the branch from which the pus was coming could be definitely located, and the small but constant ejection of pus with each cough pointed towards the right anterior branch. This branch bronchus was sucked out, but pus would appear in the mouth of the bronchus with each cough in spite of suction. The long slanting end of the bronchoscope was insinuated into this branch. It was now noted that there were many granulations in this branch which bled freely. About one ounce of bloody pus was aspirated at this time into a sterile bottle. This was examined by Dr. George S. Dixon, of the New York Eye and Ear Infirmary, who reported as follows: The pus removed bronchoscopically from the lung abscess of Mr. F. H. shows a pure culture of Friedlander bacilli. This was extremely interesting, for most of the infected ears which we see in the summer caused by swimming about New York harbor are usually due to the Friedlander bacillus, one of the colon group. This man had a lung abscess caused by the inspiration of sea water about New York harbor.

For definite lung mapping the abscess cavity was injected the following week with a mixture of bismuth subcarbonate in pure olive oil, one in three. The anterior branch of the right lower lobe bronchus was injected around a corner by a special curved spiral cannula. The bismuth mixture was injected slowly so as not to infiltrate the surrounding lung tissue. Eight c.c. of the mixture was injected, and within five minutes from this time the

*Read at the annual meeting of the American Laryngological Association, held in Boston, Mass., May 27 to 29, 1920.

patient was fluoroscoped by Dr. Charles Gottlieb and some very interesting observations were made. By fluoroscopy we were able to see the cavity filled with the opaque mixture. Plates taken before injection of bismuth did not show any definite outline of the abscess. Several plates were taken in all

FIG. 1.—Radiograph of abscess in right lower lobe of the lung. Note the dense shadow produced by "pus sponge soaking" of the lung. The outline of the abscess cavity is not clearly discernible.

positions and a set of stereoscopic plates made. Within a short time after the taking of these plates the patient was again fluoroscoped and the bismuth mixture was seen to be coming out of the abscess cavity and flowing upward. He had not coughed up to this time for he was breathing as quietly as possible. He did have considerable cough, however, immediately following the removal of the bronchoscope, but the fluoroscopic studies made by Dr. Gottlieb, Dr. Corwin and myself did not show any bismuth in the bronchi, but only in the abscess cavity. It was extremely interesting to note that, while the bismuth was coming out of the abscess cavity into the bronchi, it did not flow downward but flowed upward, and radiographic plates taken at this time showed the middle lobe and superior lobe branches well outlined by the opaque mixture, while the lower lobe branches remained free. Shortly after this the patient complained of such bubbling in his chest that he was compelled to cough and expelled about two c.c. of the white bismuth mixture. From these observations Dr. Gottlieb and myself agree that there is probably another mechanism beside cough and the action of cilia which causes the expulsion of secretions from the tracheobronchial tree. A second injection of the bismuth mixture was repeated one month later.

The injection of bismuth mixtures while done for the purpose of mapping the lung for the definite location of abscess cavities seemed to have a beneficial effect on the patient. There was no odor to the pus expectorated after the second injection and this was so striking that the patient noticed it himself and said "that he no longer had a foul breath for the bad smell and taste had disappeared."

The patient was examined radiographically and fluoroscopically one month later to ascertain how

long the bismuth remained in the abscess cavities and also how long it remained in a small area of lobular tissue into which it had infiltrated. The bismuth mixture, as previously stated, started to make its exit from the bronchial tree within a short time after injection. It is interesting, however, to note that in the abscess cavities and lobular structure it remains much longer but eventually disappears. In the abscess cavities it may remain from two weeks to two months, but the shadow gradually grows less opaque until it finally disappears. This may perhaps in a measure account for the improvement of the patient and the gradual diminution in the quantity of pus expectorated and the disappearance of odor.

CASE II.—The second patient injected was a young lady of twenty years whom I had the good fortune to see in consultation with Dr. Willy Meyer and Dr. Richard Jordan. The patient was admitted to the Lenox Hill Hospital and bronchoscoped shortly thereafter. Some very excellent radiographs were taken by Dr. William H. Stewart which showed what appeared to be a very large abscess in the left upper lobe well out towards the periphery. From the surrounding pus sponge soaked lung structure it appeared much larger than it really was and also suggested some pleural involvement. The patient had had a tonsillectomy performed by an expert laryngologist one week before admission. At the time of admission she was expectorating 250 c.c. of pus every twenty-four hours, and her general condition was poor.

She was bronchoscoped, a seven mm. tube being used. Pus was pouring out of the larynx and continued to pour out of the bronchoscopic tube. This was sucked out and the left bronchus entered.

FIG. 2.—The abscess cavity mapped out by the injection of an opaque mixture. The walls of the abscess cavity are clearly defined. The dull opaque spot above and to the right of the abscess cavity is due to the infiltration of bismuth in a minute branch bronchus well out toward the periphery which connected with the abscess cavity. The abscess communicated with an anterior branch bronchus and was injected around a corner.

There was an edematous bronchial stenosis opposite the upper lobe orifice leaving only a small opening through which pus was expelled with each cough. There was also a membranous plaque which caused further obstruction of drainage. The membranous

plaque was removed by suction. After evacuating as well as possible the upper lobe branch the lower lobe branches were examined, but no pus was found in this locality. Now the upper lobe branch was again entered and the patient instructed to cough. With each expulsive cough there would be a gush

FIG. 3.—A left upper lobe abscess following tonsillectomy. Note the dense shadow well out toward the periphery simulating pleural involvement. Dense "pus sponge soaking" of the lung made the interpretation of the abscess cavity difficult in the plates before injection.

of pus from this branch. The bronchus was apparently draining much more freely since the edematous stenosis had been opened. With a ten inch vacuum the bronchus was once more aspirated and after fifteen minutes the bronchoscopic tube was removed.

The following week the patient had improved somewhat, but the amount of pus had not greatly decreased. We again bronchoscopically aspirated the left upper lobe branch, and then decided to inject the bismuth and oil mixture to try and map out the abscess cavity. With a curved spiral cannula, eight c.c. of the mixture was injected.

Unfortunately the mixture was injected too forcibly and some of it was squirted out of the spiral and passed downward into the lower lobe branches. Leakage out of the spiral will not occur if the mixture is injected slowly, nor will it infiltrate into the lobular structure of the lung. The upper lobe branches and lung abscess were also injected; the bismuth sticking to the wall of the cavities and mapping them out. Several smaller abscesses were seen, whereas in the plate taken before injection the cavity was interpreted as being very large. The

bismuth did not infiltrate the lobular structure of the upper lobe.

By stereoscopic plates the abscess cavities were seen to be well out towards the periphery and anterior, while the mass which had leaked down into the lower lobe branches was well posterior. A lateral plate taken at this time showed the relations of the upper anterior lobe abscess cavity which was clearly defined, to the posterior dull opaque fan shaped area due to gravitation into the dorsal branch.

The bismuth was expelled from the lung as in the other patient within twenty minutes after injection. As some of the bismuth mixture had leaked downward into the lower lobe branches it was impossible to state whether or not the bismuth started immediately to be expelled outward as in the first patient or if it had gravitated into the lower lobe branches after it started to be expelled. The patient was studied from time to time with the fluoroscopic screen, and further radiographic plates were taken. At the end of one week there was still bismuth present in both the abscess cavity and in the lower lobe where no abscess existed. This bismuth soaked

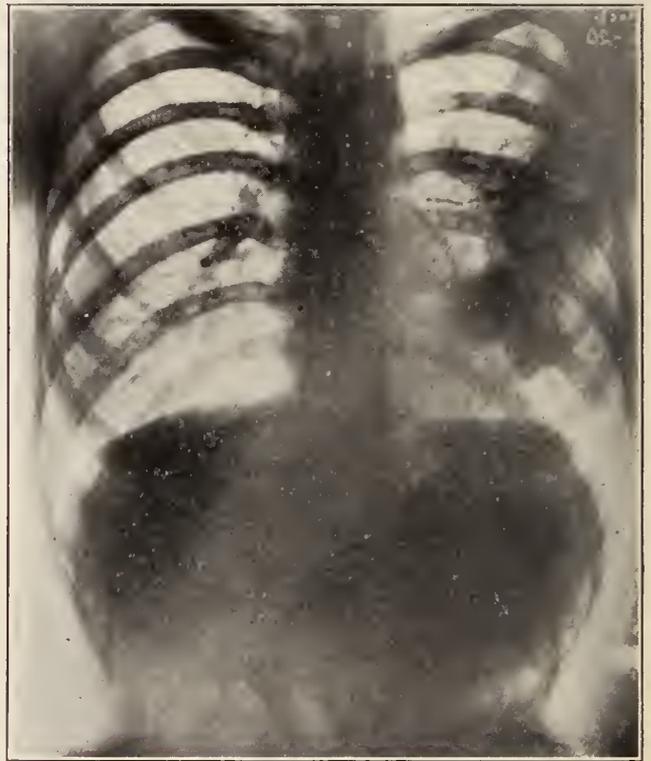

FIG. 4.—The abscess cavities injected around a corner. The lower branches of the upper lobe were injected by turning the curved spiral injector downward after introduction into the upper lobe branch. Some of the bismuth mixture leaked out of the curved spiral and gravitated into the lower lobe branches where no abscess existed. Numerous small cavities were mapped out in the original plates and there was a bright metallic lustre of the mixture in the abscess cavities. In the lower lobe where no abscess existed the bismuth mixture showed as a dull opaque spot.

area looked somewhat like an abscess cavity, but there was an irregular outline of opaque dullness and it had not the metallic lustre of the bismuth in the abscess cavity. This is one of the distinguishing points recorded by me between the infiltration of bismuth into the lobular structure of the lung and

in the abscess cavity. This patient improved after the injection in a similar manner to the other patient. The pus decreased from her lung and the amount of measured sputum decreased from 250 c.c. to 30 c.c. every twenty-four hours. The odor was decidedly less and the patient's general health improved.

The bismuth mixture was still present in the lung when plates were made ten days later, though both shadows were decreasing in density and the lung abscess was apparently clearing up. The patient has suffered no discomfort following the injections of bismuth into her lung. She eats and sleeps well and has but little cough. She has been bronchoscoped twice since the two injections and no bismuth were we able to recover by suction even though it is still present by x ray examination. At later bronchoscopic examinations there was very little pus recovered by suction, for no pus was expelled from the left upper lobe bronchus when the patient was instructed to cough.

Of course this paper is not presented with any tone of finality for it is only a short preliminary report of the study by injection of opaque mixtures for the purpose of mapping abscess cavities in the lung of the living subject.

SUMMARY.

1. Bismuth mixtures can be injected into the bronchi and lung of the living without doing harm.

2. The injection of opaque substances into the lung of the living will open up an enormous field of usefulness in the study of cough, the expulsion of secretions from the lung and lung drainage. It will also localize bronchial strictures in the same manner as seen in the esophagus. Furthermore, it will be of the greatest aid to the thoracic surgeon by mapping out the abscess cavity in the correct lobe of the lung on which he is to operate.

3. A definite lung abscess cavity is seldom seen bronchoscopically. Pus is usually seen coming from a small branch bronchus, and the abscess cavity may be well around a corner and not in a direct line with the bronchus from which the pus is oozing.

An injection of a bismuth mixture or some other opaque substance will clear up this error.

4. Bismuth when it enters the abscess cavity is interpreted in the radiographic plate

by its metallic lustre, and when it is in the lobular lung structure it is interpreted by its dull opacity. Pus diffuses and soaks the lung structure, and this often makes the involved area appear many times larger than it really is.

5. The amount of bismuth injected in these patients was an eight cubic centimetre mixture of bismuth subcarbonate in pure olive oil, one in two and one in three. The mixture is made sterile by boiling before injection.

6. The injection should be made slowly and not with a squirt, for the picture may be spoiled by bismuth lung soaking.

7. From these preliminary studies it seems that cough and the action of cilia may not be the only means of expelling secretion from the lung.

8. While bismuth mixtures were originally injected by me for purposes of lung mapping of abscess cavities in their proper lobes, it seems to have been of apparent benefit to the two patients in whom it was tried. So far it has done no harm.

Proofs of the Constitutional Nature of Cancer*

By L. DUNCAN BULKLEY, A. M., M. D.,
New York,

Senior Physician to the New York Skin and Cancer Hospital; Member American Association for Cancer Research.

Cancer has too long been studied and regarded as a purely local disease. On the other hand, evidence has been steadily accumulating all over the world that, while the individual lesions of carcinoma may be incited by local injury, the disease is really of a constitutional nature, like so many other diseases, especially in middle and advanced life. No one would think of regarding arteriosclerosis, arthritis deformans, gout, obesity, or dia-

betes as local affairs, amenable to purely local treatment, nor of expecting to accomplish anything of importance by excising the late lesions of syphilis or tuberculosis. As yet the medical profession and laity are slow in accepting the now well recognized constitutional relations and nature of cancer.

Not to go back too far, over a hundred years ago the great English surgeon, Abernethy (1), very earnestly said: "There can be no subject which I think more likely to interest the mind of the surgeon than that of an endeavor to amend and alter the

*Read before the American Association for Cancer Research, March 24, 1921.

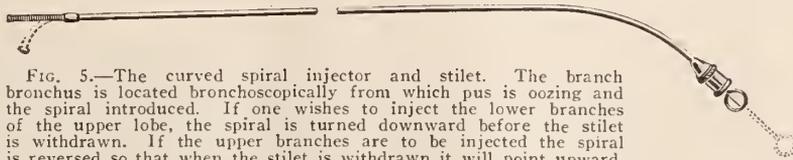

FIG. 5.—The curved spiral injector and stilet. The branch bronchus is located bronchoscopically from which pus is oozing and the spiral introduced. If one wishes to inject the lower branches of the upper lobe, the spiral is turned downward before the stilet is withdrawn. If the upper branches are to be injected the spiral is reversed so that when the stilet is withdrawn it will point upward. Leakage of the curved spiral may be obviated by applying a coating of flexible collodion to it. The collodion should be thoroughly dry before introduction of the spiral. This will prevent leakage and thereby overcome misinterpretation of the radiographic picture.

state of a cancerous constitution. The best timed and best conducted operation brings with it nothing but disgrace if the diseased propensities of the constitution are active and powerful. It is after an operation that, in my opinion, we are more particularly inclined to regulate the constitution, lest the disease should be revived or renewed by the disturbance."

Over seventy-five years ago Walshe (2), in his masterly treatise on cancer in all its relations, gave numerous references, original or quoted from recognized authorities, in regard to the constitutional nature of cancer, as well as expressions in regard to the futility of expecting that surgical interference could cure the disease in any great proportion of cases. He says: "It would in theory appear that the removal of a tumor cannot of itself cure the disease, as the local formation is but a symptom of a general vice of the economy. . . . This tissue being, as the normal textures, the seat of nutrition, is, like them, susceptible of its disordered actions." Sir Astley Cooper (3), a great surgeon, had some time before expressed the same views.

Over fifty years ago, Sir James Paget (4), that prince of pathologists and surgeons, spoke very strongly in regard to cancer: "I believe it to be constitutional, in the sense of having its origin and chief support in the blood, by which the constitution of the whole body is maintained. . . . The existence of the morbid material in the blood, whether in the rudimental or in the effective state, constitutes the general predisposition to cancer."

Nearly forty years ago, Dr. Willard Parker (5), one of New York's greatest surgeons and a wise physician, in a study of 397 cases of cancer of the breast, spoke very strongly on the subject. He says: "Cancer is to a great degree one of the final results of a long continued course of error in diet, and a strict dietetic regimen is, therefore, a chief factor in the treatment, preventive and curative." After speaking of the surgical removal of a cancerous breast, he says: "We must then adopt the means stated above to prevent a second development. We must change the diathesis; we must seek to modify the patient's constitution, so that it will no longer be prone to reproduce the disease; and then only may the surgeon be satisfied that he has done his duty."

During all this period, and since, very many others have promulgated the same views, with more or less earnestness and persistency. One of these is Sir Arbuthnot Lane, who a few years ago emphasized the fact that one of the terminal results of intestinal stasis may be cancer.

Dr. Forbes Ross (6), also of England, wrote very strongly of the constitutional nature of cancer, giving illustrative cases, and his untimely end soon after the publication of his book robbed the cause of an intelligent and earnest worker in the field. Having been a very active operator on cancer, and seeing the unfortunate results of operation, he took up the study of the blood and cancer, adducing very strong arguments and illustrations of the constitutional nature of the disease.

One of the most ardent supporters of this line of thought is Robert Bell (7), of London, whose intel-

ligent and clever books have never been taken seriously enough. Having also been a surgeon for cancer for fifteen years, and experiencing the ultimate bad results of the same, he abandoned surgery in 1894 and has written volubly on the dietetic and medicinal treatment of the disease, with illustrative cases.

The late Dr. John B. Murphy, of Chicago, has repeatedly expressed himself in his clinics (August, 1912, to June, 1914) most pessimistically in regard to the ultimate results of the surgical treatment of carcinoma, especially in those patients who are fat and have lax tissue, that is, exhibiting evidence of imperfect metabolism.

The latest, and under the circumstances the most important, supporter of a constitutional nature of cancer is Dr. William J. Mayo (8), who, in his president's address before the American Surgical Association, spoke in a manner which should attract serious attention. Few have had wider acquaintance with the surgical aspects of the disease than he, and few others know better than he how relatively impotent surgical procedures are to stay the steadily increasing mortality from cancer, which now claims about ninety per cent. of those whom it once attacks. Speaking of the prophylaxis of cancer, mainly from its surgical aspects, he says: "Cancer of the stomach forms nearly one third of all cancers of the human body. So far as I know this is not true of the lower animals, nor of uncivilized man. . . . Is it not possible, therefore, that there is something in the habits of civilized man, in the cooking or other preparation of his food, which acts to produce the precancerous condition? . . . Within the last hundred years four times as much meat has been taken as before that time. If flesh foods are not fully broken up, decomposition results and active poisons are thrown into an organ not intended for their reception, and which has not had time to adapt itself to the new function." In conclusion he says: "Where cancer in the human is frequent, a close study of the habits of civilized man, as contrasted with primitive races and lower animals, where similar lesions are conspicuously rare, may be of value, and, finally, the prophylaxis of cancer depends, first, on a change in those cancer producing habits, and, second, on the early removal of all precancerous lesions and sources of chronic irritation."

But all these warnings, and many more, seem to have been ignored and lost on the profession at large, and surgery is still regarded as the only hope for cancer, in spite of the demonstration that under its rule the mortality from cancer has risen steadily, since 1900 nearly thirty per cent., while that from tuberculosis has fallen about the same amount under proper medical care. Indeed, in 1915, the year after active surgical propaganda throughout the country, through the influence of the American Association for the Prevention of Cancer, the actual rise in the mortality from cancer, as shown by the United States Mortality Tables, was double the percentage of the average rise of the five preceding years. Moreover, in New York city, from July 1 to December 31, 1920, the number of recorded deaths from cancer, 2,691, exceeded those from

tuberculosis, 2,669, by twenty-two! The reasons for the lamentable condition in which carcinosis as a disease stands today, in regard to its treatment and ultimate results, are not difficult to discover, and may be briefly mentioned:

1. The glamor of surgery, and latterly of x rays and radium, and the craze for immediate and spectacular results.

2. The claims of the surgeons as to the success of operations, and the failure to record and report end results, after the lapse of years.

3. The results of laboratory and research work, wrongly supporting surgeons as to the local nature of carcinosis, and advocating the desirability of the immediate removal of the results or products of it, now called cancer.

4. Ignorance on the part of the general medical profession as to the true facts concerning cancer.

5. The many fake cancer cures which have been foisted on innocent sufferers, together with the many failures of remedies and measures which have been advocated by the regular medical profession.

I shall not discuss these points, which, I think, will be recognized and acknowledged by all, but will proceed to present, very briefly, facts which point unerringly to the proof of the constitutional nature of cancer. In order that these may appear clearly and appeal properly to the understanding of my readers, I have drawn them up in tabular form.

PROOFS OF THE CONSTITUTIONAL NATURE OF CANCER.

I. Laboratory findings	{ Negative { Cancer is not parasitic. Cancer is not contagious nor infectious. No cause for cancer has been found.
	{ Positive { Cancer cells are but altered normal cells. Feeding experiments show a possible control of cancer growth.
II. Statistical evidence	{ Contrast of death rate since 1900 between cancer and tuberculosis. Steady increase of cancer deaths under active surgery, x rays, and radium.
III. Biochemical evidence	{ Blood changes in early and late cancer. Metabolic changes in the system before and after the development of the local cancerous lesion.
IV. Clinical evidence	{ Opinion of many celebrated surgeons during the last hundred years to the present time. Spontaneous cures of cancer well authenticated. Dozens or hundreds of attested cases of benefit or cure of cancer by other than local measures, in this and other countries.

Most of the items on this chart are so thoroughly known and accepted, or are so selfevident that we need not waste time in considering them; but looked at in their entirety the total evidence of the constitutional nature of cancer is fairly convincing.

While cancer has been found to be neither parasitic nor infectious, and after years of laborious and honest laboratory research no cause of cancer has been found, does it not seem natural to question whether the research has been in the right direction, and if scientific investigation has been following the right clue? Has it not been following anatomical and experimental lines to the too great exclusion of physiological and clinical lines? For, as Pope says: "The proper study of mankind is man," and man is

a living being, and in a practical way physiology is more than histology in the actual life of man and his diseases. But, on the other hand, laboratory research has in a measure cleared the way along certain lines for the study of cancer which are bright with promise. All agree that cancer cells are only body cells, once healthy, which have thrown off their allegiance to normal control, leaving their natural function of secretion, etc., and expending their whole energy upon growth, which we call malignant because of the harm which we observe to result from their action.

Now, repeated laboratory experiences, by a number of reliable observers, have demonstrated in a most remarkable way the absolute controlling effect of diet on the development of inoculated cancer in mice and rats, so that the process was inhibited almost entirely by certain vegetable feedings. Does this not stimulate us to try to discover wherein this mysterious influence lies? Does it not suggest that possibly the outrageous conduct of the cells has something to do with the pabulum with which they had been nourished? Even as mutiny in a regiment or on shipboard might be started by one or more men who rebelled at the quality or quantity of the food furnished, and then be spread to many others, with new groups developing, until the errors were corrected.

The mortality of tuberculosis and cancer have often been compared and teach us a lesson along these lines, although in a different direction; the death rate of the former during the last twenty years has fallen, under wise medical direction, about thirty per cent., while that of cancer has risen almost the same thirty per cent., under active surgery, x rays and radium, because they were operating on the mistaken idea that cancer was a local affection. Both tuberculosis and cancer have to do with nutrition, but at opposite poles. The tuberculous subject is underfed and overworked, while the cancer patient is overfed or wrongly fed and underworked. In the former poor nutrition allows the operation of the omnipresent tubercle bacilli; in the latter certain individual cells rebel and mutiny. When the tuberculous patient is properly nourished, including oxygen, he ceases to furnish the necessary nidus for the bacilli, and when the cancer subject is nourished with a proper blood supply the rebellious cells return to their allegiance, as would the soldiers or sailors, if an intelligent officer rectified their errors of nutrition.

The biochemical conditions of the system, both in early and late cancer, attest the constitutional nature of the disease carcinosis, of which the masses we wrongly call cancer are but the product; just as the various lesions in tuberculosis, gout, syphilis, and leprosy, are not the disease itself, but are only its symptoms. All are familiar with the blood changes occurring in cancer; but unfortunately most of those known relate only to the corpuscular elements and not to its plasma, which has received the partially elaborated products of digestion, and the results of the metabolism of the system through the thoracic duct, and from which the corpuscular elements are formed and the individual cells of the body are nourished. Time does not permit of the

elaboration of all this matter, which has been abundantly treated of elsewhere. But to one who has watched and studied carcinosis in all its medical and surgical aspects for many years, it seems strange that there can be doubt in any one's mind regarding the constitutional nature of the disease, and the unreasonableness of attempting to check it permanently by simply attacking its local manifestations in various parts of the body. The spontaneous cures of well authenticated cases of cancer should teach us that, just as at some particular time a condition of system arose which led to the formation of a malignant neoplasm, possibly from a local injury, more often not, and then later something else occurred which led to the return to normal of the disordered cells, so medical acumen should seek to discover the latent reason of this, and medical skill should devise proper measures to correct it; and this has been done.

Finally, in regard to many matters in medicine we are all willing to regard intelligently and accept the judgment and views of those who have had wide experience along particular lines of thought and activity. But in regard to cancer, a mental obliquity, obtuseness, or something, seems to have taken possession of the entire medical profession, and also of the laity, to such a degree that they will not accept any cause of cancer unless it is absolutely proved by laboratory research. In regard to no other disease has there been such an imperative and insistent demand for a definite, established, proved and recognized cause as there has been in regard to cancer.

Now, no higher authorities could be quoted in favor of a constitutional nature of cancer than those

given at the opening of this address. The opinions from experience of many justly celebrated surgeons and physicians, from Abernethy, one hundred years ago, to J. B. Murphy and William J. Mayo of the present time, besides many others not mentioned, should quiet these unreasonable demands.

At the same time, the hundreds of cases of undoubted cancer which have been seen by many of us to yield to internal measures, even including various serums, should be enough to convince the most sceptical of the constitutional nature of cancer. This is especially true in view of the lamentable and terrible increase of mortality from the disease, under the local views held so strongly by many, since the days of Virchow, Cohnheim, and Ribbert, and the utter failure of local measures, such as surgery, x ray and radium, to check the advance of cancer racially all over the world.

Neuralgias of the Superior and Inferior Maxillary Branches of the Fifth Nerve Caused by Dental Pulp Nodules*

By N. PHILIP NORMAN, M.D.,
New York,

Late Major, Medical Corps, U. S. Army; Consultant in Neuropsychiatry,
and

HOWARD M. JOHNSTON, D. D. S.,
Berkeley, Cal.,

Late Lieutenant, Dental Corps, U. S. Army, Fort D. A. Russell, Wyo.

INTRODUCTION.

Neuralgia, defined in its primary sense, means pain, or a painful sensation of a definite type, limited to the sensory distribution of a peripheral nerve, or nerves. This pain may be referred to the surface distribution of the affected nerve, pressures on the areas of which causes a typical but not severe pain, which we are pleased to term neuralgic in character.

The neuralgias are differentiated from the neuritides, in that they are considered only as an affection of a peripheral sensory nerve, while neuritis is thought of as an affection of a mixed nerve—motor and sensory. This is a clinical differentiation.

The pathological differentiation is that in the neuralgias there seems to be no constant definite relation of pathological change to clinical symptoms, whereas, in the neuritides, tissue change is not infrequently demonstrated by microscopic methods, and there is a relationship of pathology to clinical symptoms.

In treating the neuralgias, our therapeutic resources are directed to a temporary or permanent relief of the chief symptom, pain.

Diagnostic technic should be exhausted in an attempt to ferret out the productive factor or factors of the pain, and to search for any associated pathological condition or conditions that may be the instigator of the local agent to dynamically react upon a peripheral sensory nerve.

*Read before the Schuyler County Medical Society, February 15, 1919.

Even though one be fortunate enough to locate the local cause of irritation and remove that cause, if associated or coexistent constitutional pathological processes are ignored, it is to be expected that, in the majority of instances, disappointment will occur to patient and physician. This is especially true of

gums), syphilis; the exogenous and endogenous intoxications; nonprogressive convalescent states following acute infections and surgical procedures with pyogenic complications; the metabolic diseases with their associated endocrine disturbances; tumors of the Gasserian ganglion, of the brain, of bone in the adjacent vicinity or inflammation of the bony structures within the neighborhood of the nerve. Indeed, it may at times be the initial symptom of tabes dorsalis, and Oppenheim cites a case of multiple sclerosis beginning as a facial neuralgia.

Neuralgias of the fifth nerve, having a psychological etiology, have been reported and are designated as psychalgias. They are amenable to suggestion therapy and psychoanalytical investigation. These cases should impress upon one the necessity of attempting to correctly evaluate the psychological content of a patient's mind, whether or not one suspects an hysterical or a neurasthenic makeup, for, indeed, it would be a serious reflection upon the intelligence of one who would extract teeth, devitalize teeth, or resort to surgical means, as alcoholic injections, avulsions, extirpation of the ganglia and section of the fifth nerve, in cases of psychological etiology.

In the following discussion the subject matter will be limited to the neuralgias of the superior and inferior maxillary divisions of the fifth nerve, caused by dental pulp nodules. For a number of years pulp nodules have been recognized as the excitant factor of some cases of neuralgia of the superior and inferior maxillary divisions of the fifth nerve.

It is the purpose of this article to emphasize the necessity of excluding the presence of pulp nodules in apparently normal teeth, in all cases of intractable neuralgia, before one hopelessly resigns oneself to a state of helplessness in treating these cases. Pulp nodules in apparently sound and healthy teeth, with little or no reaction to the ordinary tests, are difficult of diagnosis. Pulp nodules, present in decaying

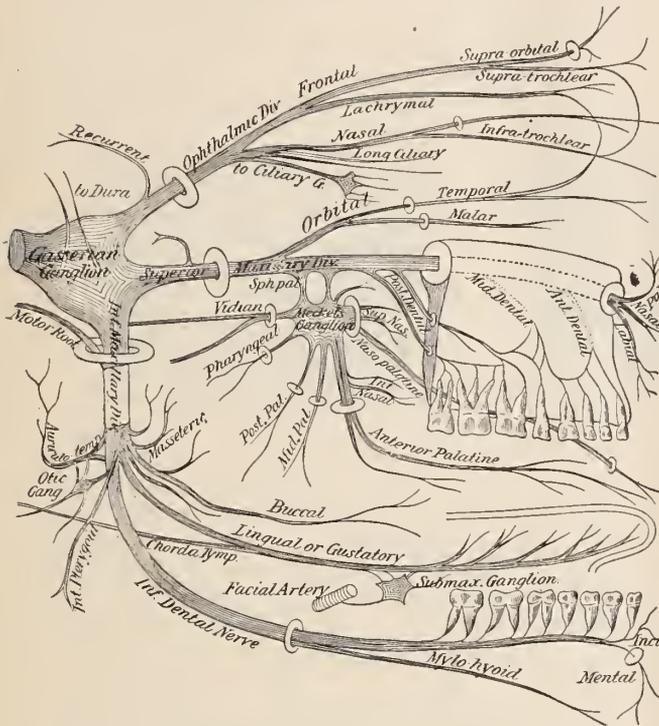

FIG. 1.—A schematic outline of the distribution of the fifth nerve, from Porter's *Quiz Compend of Anatomy*. P. Blakiston's Son & Co.

the quintus neuralgias, because of the widespread distribution of the fifth nerve and the intimate relationship that this nerve has to bone and bone cavities, as well as the number of constitutional diseases frequently found associated with these neuralgias.

The frequency of the occurrence of quintus neuralgias leads us to believe that it has a greater tendency to neuralgic involvement than any other nerve of the body. It is believed that the superior and inferior maxillary branches of this nerve, because of anatomical distribution, the intimate relation that they have with the teeth and the relatively exposed positions of their terminal filaments, are subject to a multiplicity of irritations that account for the predominating frequency of quintus neuralgias.

The causes of trigeminal neuralgia are many and are mentioned for purposes of review as follows: The teeth play a predominant rôle, perhaps undergoing a constructive or destructive pathological change, or, because of a constitutional defect in shape, position or development; affections of the gums, of the jaw bones, the cranial sinuses and the mastoid, frequently produce neuralgias of the fifth nerve and associated neuralgias that are difficult to differentiate from a regional point of view; diseases of the eye, as iritis, cyclitis, iridocyclitis; diseases of the ear; constitutional diseases, as arteriosclerosis, malaria, anemias, diabetes mellitus (this disease being particularly prone to attack the teeth and

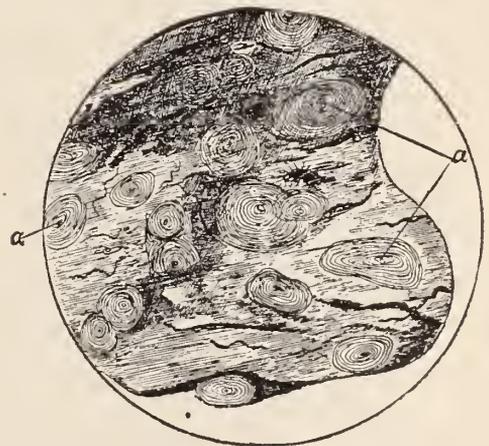

FIG. 2.—A section of the pulp nodule showing many calcospherites, as pointed out by a. a. (By permission of Professor Black, from Black's *Special Dental Pathology*.)

teeth, are comparatively easy to detect, and their removal is but part of the operation, extraction or devitalization deemed necessary by the operator for that particular tooth.

PULP NODULES.

Pulp nodules are small masses of calcic material suspended in the pulp substance which, by reason

of their progressive formation, effects a mechanical displacement to the point of strangulation, with resultant death of that tissue. They are commonly found in the bulb portion of the pulp, but may occur in the root portion, assuming a number of forms, those in the bulbar portion being round or nodular,

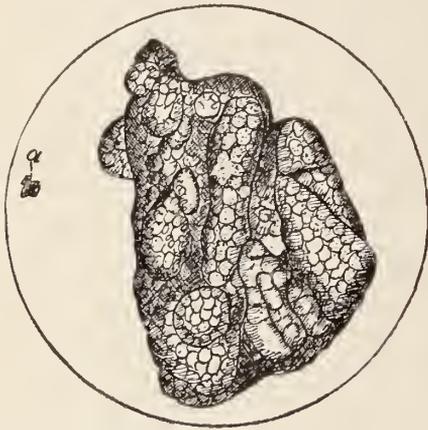

FIG. 3.—A small pulp nodule as seen with a low power, showing its nodulation; a, represents the actual size. (By permission of Professor Black, from Black's *Special Dental Pathology*.)

while those in the root portion are fusiform or spindle shaped. They are more frequently multiple than single, and it is believed that the larger nodules are formed by the coalescence of the smaller ones.

Histologically, they consist of an amorphous, translucent substance of a brittle consistency. Occasionally, concentrically laminated bodies, called calcospherites, are found irregularly interspersed throughout the nodule. Why pulp nodules form is still a matter of speculative conjecture. Black reasons that pulp nodules are the homologues of phleboliths, and believes that the calcifications are formed from a solution of albumin, calcium salts, and an excess of carbon dioxide, the result of venous stagnation. The authors believe that pulp nodules are not necessarily the result of a local circulatory or metabolic disturbance, but a localized manifestation, in some cases, of a constitutional metabolic disturbance or dysfunction, much after the same manner as the calcifications in arteriosclerosis.

In many instances it appears that abrasions, erosions and slowly progressing caries are responsible for their formation; however, this is by no means the rule, for they occur in teeth free from irritation or pathological attack. These nodules are usually found in the teeth of persons in or past middle life, but occasionally occur in youth.

SYMPTOMATOLOGY OF PULP NODULES.

There appears to be no relationship between the frequency of occurrence of pulp nodules and the production of symptoms. They do not produce symptoms with any degree of consistency. They may be present and apparently do no harm, and, conversely, their presence may initiate an irritation of the terminal dental nerve filament because of mechanical pressure.

It is a reasonable assumption that these nodules should produce symptoms in every case, but the converse is true in the majority of instances, para-

doxical as it seems. This discrepancy between cause and effect may be accounted for by their slow formation, permitting the dental pulp to accommodate itself to the change within its tissue, without giving rise to symptoms.

However, it appears that when the nodule or nodules become large enough to strangulate or obliterate the pulp tissue, symptoms are produced. The symptoms are the result of mechanical irritation, by the nodule or nodules, to the terminal nerve filament within the pulp tissue. Usually the local symptoms are hyperesthesias, not limited to the particular tooth or teeth affected, but affecting the pulps of all the teeth on that side of the dentures. Black has noted that general pulp hyperesthesia may be the precursor of an acute gouty or neuralgic attack.

Unless the nodule or nodules are located and removed, continuous pain stimuli are transmitted by that branch of the fifth nerve supplying the affected tooth or teeth. It is known that if a sensory nerve transmits continuous pain stimuli, fatigue will result. Fatigue is the end result of biological changes, in nerve tissue, necessary for the performance of specific function. If fatigue is prolonged by reason of constant irritation (pain) to a terminal dental nerve filament, neuralgia of the main nerve trunk results, with reflex neuralgic manifestations in its branches. This explains why the neuralgia does not disappear until some time after the local agent is removed. Time is necessary for a complete recuperation of the nerve itself.

DIAGNOSIS.

After excluding all probable etiological factors, excepting calcifications occurring within the pulp chambers of teeth, it is believed that a thorough search should be made for pulp nodules. The only definite means of determining whether or not they exist is by radiographs. In many instances, because of some fault in the technic, these nodules are not revealed on the film, emphasizing the necessity of making repeated exposures before one excludes their presence. Unless all the teeth, upper and lower, of the affected side be radiographed, the search for nodules will not have been thorough.

Percussion, thermal and electrical reactions and transillumination are of no definite value in the diagnosis of these nodules. One may be led to suspect calcific formations in the pulp tissue of

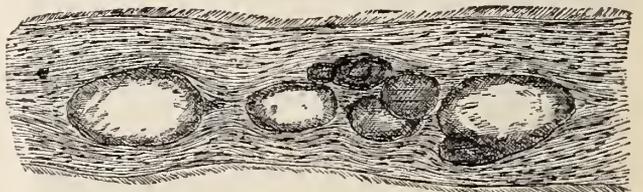

FIG. 4.—Pulp nodules in the canal portion of the pulp. (By permission of Professor Black, from Black's *Special Dental Pathology*.)

teeth that are abraded, eroded, or in teeth containing large metallic restorations; however, this is by no means axiomatic. To repeat, the diagnosis of pulp nodules is possible only by means of careful radiographic procedures, and the search should include all the teeth, upper and lower, on the affected side.

TREATMENT.

Much unnecessary disfigurement has been done by the promiscuous extraction of teeth in an attempt to relieve a neuralgia in which a positive diagnosis of the existence of a pulp nodule had not been made.

In many instances the local symptoms are referable to an unaffected tooth, and this again emphasizes the necessity of the radiographic localization of pulp nodules.

Having determined the affected tooth or teeth, devitalization of the pulps of the affected teeth is

of the trouble. It seemed that the hyperesthesia was centred about this tooth. Despite the clinical subjective evidence, radiographs facilitated the localization of the pulp nodule, the extraction of the right tooth, and gave her the much desired relief. Otherwise, the wrong tooth would have been pulled, with resultant disfigurement, the loss of a useful tooth, and no relief from the pain. Unfortunately, this case was not studied clinically, and there is no data concerning her past history or of her present physical status. This case was

FIG. 7.—Radiograph showing a calcification occurring in the mesial horns of the pulp of the lower first molar.

the only treatment after orthodox treatment of the local and constitutional manifestations have failed.

One should be conservative in the ruthless destruction of pulps in apparently sound teeth, even though pulp nodules have been radiographically demonstrated, without first attempting to correct constitutional disturbances, excepting in the cases in which a large nodule almost or completely fills the pulp chamber. However, if the usual therapeutic measures fail to give relief, one should not hesitate to sacrifice the pulp of an affected tooth, for the value of the pulp of a tooth is insignificant when compared to the relief of an intractable neuralgia.

The favored method of devitalization is either by pressure anesthesia, using cocaine or phenol, or by conductive anesthesia.

CASE REPORTS.

CASE I.—Miss X., a girl of twenty years, came for treatment because of a severe trifacial neuralgia of the left side of her face. She believed that the pain was of dental origin, and insisted that the upper left first molar be extracted. Her reason for this belief was that this tooth had been devitalized, and previous to its devitalization had caused her much pain. Radiographs revealed the presence of a pulp nodule in the upper left wisdom tooth (Fig. 2). This tooth was extracted. Upon dissection of the extracted tooth, the diagnosis was proved to be correct, as a pulp nodule almost completely filled the coronal portion of the pulp chamber, and, through mechanical pressure, initiated the irritation of the terminal dental nerve filament in the dental pulp, and in this way produced a severe superior maxillary neuralgia. This tooth was extracted because of its inaccessibility for properly filling the root canals (the roots being tortuous) and because of its comparative uselessness. This case teaches one the necessity for the absolute localization of the affected tooth, as the patient was convinced that the upper first molar was the seat

observed from the clinic of the Dental Infirmary of the University of California in the fall of 1917.

Upon Dr. Johnston's return to the infirmary, after his discharge from the service, he found that this girl had returned to the clinic, complaining of an acute toothache. She told the dentist of her former trouble, and he x rayed her teeth and found that the lower first molar was badly abscessed. The tooth looked normal; that is, there was no evidence of exposure of the pulp or any large fillings which would have caused a devitalization of the pulp with the resultant abscess. Pus was discharging at the free border of the gum around the neck of the tooth, having burrowed its way along the roots of the tooth. The radiographs revealed a large pulp stone in the first left lower molar and a smaller one in the second left lower molar. This pulp stone in the first molar had enlarged to the extent of strangulating the pulp, causing its death and the resultant abscess. The tooth was extracted after the acute stage had subsided, and dissection again proved the correctness of the radiographic diagnosis. This emphasizes the necessity of x raying all of the teeth, for if calcification is shown to exist in one tooth, there is a reasonable assumption that there is a tendency for similar changes in other teeth. Had this fact been known when pulp nodules were first demonstrated in the upper left wisdom, and had the other teeth been radiographed, this large nodule in the first left lower molar would have been found, and, fearing that it might cause either a neuralgia or a devitalization of the pulp, it would have been justifiable to remove the pulp and the nodule. This would have saved her the loss of the tooth and prevented the suffering from an abscessed tooth. From the looks of the nodule in the second molar it appears that this tooth is doomed in short time to come. The thing to do is to devitalize the pulp, remove the contents of the pulp chamber, and fill it while it is in an aseptic condition.

CASE II.—Mrs. Y., aged thirty-four; referred for treatment of an intractable trifacial neuralgia of several months' duration. Patient developed normally, had the usual diseases of childhood, and at the age of eighteen had typhoid fever. Had otherwise been very well up to the past two years, when she began putting on weight, gaining in two years' time thirty pounds. Her menses became irregular and scanty at this time. She was excessively fond of sweets, and complained of always being thirsty. Her family history was negative. Physical examination revealed a decayed wisdom tooth, slightly enlarged and congested tonsils, a negative chest, a large, pendulous abdomen and a flabby skeletal musculature. Urine showed a three and four tenths per cent. glycosuria, with no acetone or diacetic acid, the blood Wassermann was negative, the blood count showed a moderate anemia with a proportionate diminution of the red blood cell count. The decayed wisdom tooth was extracted and oral hygiene instituted. She was placed upon a diabetic regimen and upon small repeated doses of aspirin for the trifacial neuralgia. After two weeks of this treatment she became sugar free, had lost nine pounds in weight, and felt physically improved, but the neuralgia persisted. It was decided to x ray her teeth, and in the lower left first molar was found a pulp nodule (Fig. 3). The tooth was devitalized and the nodule removed. She did not recover immediately, but the pain gradually subsided until at the end of three weeks she was practically free of it.

At the end of two months the pain had entirely disappeared and the patient was discharged as cured. Apparently a constitutionally metabolic disorder had occurred some two years previous, which had not been attended to, and the nodule was most likely a localized expression of the general metabolic disharmony. There does not appear to be other nodules in her teeth, and the likelihood is that if she remains under intelligent supervision they will not develop.

So far as we know, two such cases have never been published before. While they perhaps have occurred in the practice of a great many men, at the same time it is not believed that such has been reported. The authors would be glad, indeed, to receive the cooperation of dentists and neurologists throughout the country in reference to the production of trifacial neuralgia by pulp nodules. Additional case reports may serve to teach us some facts that may be pertinent in excluding pulp nodules as a cause of trifacial neuralgia. While we recognize that a great many men have been able to demonstrate that a nodule has been the excitant factor of a trifacial neuralgia, yet the point we wish to make is that the pulp nodule can be and should be radiographically demonstrated, not only in decayed teeth but in teeth that are apparently healthy and sound.

The Influence of the Prostate on the Health of the Man Past Middle Life*

By H. G. BUGBEE, M. D.,
New York,

Attending Urologist to St. Luke's Hospital.

The health of the individual may be summed up as the result of proper intake, assimilation, and elimination. The last is the most vital, failure of elimination causing a storing up in the system of toxic products, with damaging effects upon all the body tissues, resulting in impaired function of the vital organs. Elimination is carried on by the skin, intestinal tract and kidneys. The process, as incorporated in the action of the bowels and kidneys, must have a free channel for its excretion to the point of exit, i. e., anus and meatus. No matter how perfectly the kidneys functionate, urine excreted must have free passage through the ureters to the bladder, and from the bladder to the external meatus.

At the outlet of the bladder the prostate holds a crucial position. When we realize that between thirty and forty per cent. of all normal men show hypertrophy before the age of sixty and that relatively forty per cent. of these present symptoms, the importance of the proposition is at once apparent.

Fully twenty-five per cent. of patients presenting symptoms from prostatic obstruction come to us with carcinoma, thus adding to the severity of the problem. The changes which the prostate undergoes in men past middle life are degenerative, rather than hypertrophic, being glandular, resulting in enlargement of the organ; fibrous, causing shrinkage and hardening, or carcinomatous. Symptoms resulting from these changes are due to encroachment upon the lumen of the vesical neck from enlargement of the prostate, or contraction of the neck, with fixation, and narrowing of the lumen. While prostatitis and prostatic abscess are encountered at this age, they are rare in the absence of hypertrophy.

Realizing, then, that prostatic degeneration in the form of hypertrophy, fibrosis, or carcinoma takes place before the age of sixty in forty per cent. of all men, let us see what symptoms are first encountered, and what bodily changes take place as a result of this prostatic retrogression.

Since the prostate, by means of its lobes, surrounds the vesical neck, changes in its contour, size

*Presented before the Springfield, Mass., Academy of Medicine, October 12, 1920.

and consistency, easily interfere with bladder drainage by encroachment upon the lumen of the vesical outlet, or, by a hard ring, prevent the internal vesical sphincter from functioning properly. The first symptoms, therefore, will be those connected immediately with the primary function of the bladder, namely, the proper emptying of the reservoir.

Probably the first noticeable sign, which is often overlooked, is diminution in the size of the stream and a slightly increased voluntary effort on the part of the individual to expel the urine. This increased effort causes congestion of the vesical neck, which, in turn, gives rise to an increased desire to urinate. Disturbed function of the internal sphincter, allowing urine to leak into the prostatic urethra, causes more constant pressure on the external sphincter and further increases the desire to urinate. The patient begins to get up at night to void. There may be an interrupted stream. He notes that if he relaxes while the urine runs slowly, in time he completes the act. This is due to the ball valve action of the prostate which is often present early in the hypertrophy.

Change in the size and force of the stream, increased frequency, and intermittency, with dribbling at the end, are the first symptoms of prostatic change; and, while slight at first, in all probability will increase in severity with the progression of the pathological process. As the obstruction of the vesical neck becomes more complete, actual inability to empty the bladder takes place and residual urine collects in varying quantities. The bladder increases its effort to empty itself, resulting in hypertrophy of the muscle bands and giving way of the weaker places in its wall, with the formation of pockets. Frequency of urination now becomes directly proportionate to the amount of residual urine. The bladder fills more rapidly than usual, as it is never empty. This symptom is particularly distressing at night. I have known such a condition to progress until the patient, on first seeking advice, was incontinent at night from the fact that the bladder was always full and overflowed when the individual was asleep.

In time the bladder, from its increased activity, becomes dilated and weakened, and its efforts become feeble and more frequent. The process does not end here. The back pressure extends up the ureters to the kidneys, resulting in ureteral dilatation, pelvic dilation, and interference with kidney function. Congestion of the kidneys leads to polyuria, thus increasing the frequency. Interference with kidney function means poor body elimination which, in turn, affects all body tissues and all organic functions, with constitutional and local symptoms referable to each. The foregoing is the order of changes which take place. Some cases seen early in the retrograde prostatic change progress slowly under medical supervision.

So far we have considered the sequence of pathology and symptomatology, with the maintenance of an uninfected urinary tract. The kidneys eliminate toxic products, rendering the urine irritating, while bacteria in varying numbers are usually present in the urine. No harm results until the stasis takes place, with the presence of which inflam-

mation often supervenes spontaneously, or with the first internal manipulation of the physician, or soon thereafter. With the onset of infection all symptoms increase to a distressing degree, and the health of the individual suffers proportionately from added septic absorption.

We have, therefore, a lesion which is progressive, leading to far-reaching complications, and which, if left to itself, results in impaired comfort, efficiency and health, eventuating in invalidism in a considerable proportion of men past middle life. It is therefore a subject of great importance. How shall we cope with it? How can this prostatic degeneration be prevented?

ETIOLOGY.

The etiology of the condition is uncertain. Dependence upon infection is doubtful, as the process is one of advancing years and well past the usual period of venereal infection. The urine in early cases often reveals no evidence of infection caused by other pyogenic organisms. The prostates of practically all men past middle life are shown, on microscopical study, to be subject to the same adenomatous change which, in its more complete development, is called prostatic hypertrophy.

All factors that lead to congestion of the prostate, as inflammation, sexual excess or irregularity, sedentary life, and poor elimination undoubtedly predispose to the degenerative change; and it is fair to say that the prostate shares in the general well being of the individual who maintains a physical and mental equilibrium through proper intake, elimination, exercise, and sexual life, without undue mental stress.

The periodical physical examination of males past middle life may make it possible for us to detect the first signs of prostatic change in a large proportion of men; and by studying more cases in this stage, to arrest its progress, to alleviate the symptoms by minor procedures, to radically cure the condition by removal of the gland before secondary changes have caused permanent damage, and to detect carcinoma at a time when it can be handled to better advantage.

As a basis for what I shall have to say regarding the handling of cases presenting disturbances of urination sent to me as prostatic cases, I wish to briefly summarize 204 male patients of this type seen in private practice during the past year. Hospital cases have not been included in this group, as it is difficult in this class of patient to adopt the régime most satisfactory and to follow them carefully.

Of these cases fifty-two presented a clearcut adenomatous enlargement or so-called hypertrophy. Of these fifty-two, thirty-six were operated upon, the prostate being removed. Seven others are under observation, the condition not being extensive enough to make operation imperative at the present time, although it was advised in four of these seven. Seven others presented complications without severe symptoms, the symptoms being relieved by the elimination of the complications. Two, given suprapubic drainage, have not yet come to prostatectomy. Two of these patients were under fifty years of age; four between fifty and sixty; twenty-one between sixty and seventy; eighteen between seventy and eighty; two between eighty and ninety.

Four patients presented a small fibrous prostate. In one the prostate was removed, and in the others the hard ring was released by the removal of pieces with the intraurethral punch. The ages in this group were sixty-seven to seventy-four.

The largest group of cases comprised those presenting urinary symptoms in which a true hypertrophy could not be demonstrated, but in which a slight enlargement or hardening in whole or part of the prostate was present, often due to congestion, sometimes a beginning hypertrophy, in others a slight infection accompanied by a seminal vesiculitis. In none of these cases was the prostate removed. They form a type that requires observation—some a punch operation, others a destruction of tissue about the vesical neck by fulguration, others massage and the institution of measures tending to reduce congestion. Sexual excess, irregularities and continence played an important rôle in these cases.

Two of the patients of this group were under forty years of age, forty-five between forty and fifty, twelve between fifty and sixty, five between sixty and seventy, and one over seventy.

Carcinoma of the prostate was found in twenty-one cases, a strikingly large number even for private cases, patients who are expected to seek advice earlier than hospital cases.

Seventeen of these patients were treated by suprapubic drainage or radium or both. Their ages were: under sixty, two; sixty to seventy, six; seventy to eighty, eight; eighty to ninety, one.

There were five cases of bladder calculus, two of prostatic calculi, eight of stone in the ureter giving urinary symptoms only, two of renal calculi, four of pyelonephritis or pyonephrosis, nine of stricture of the urethra, ten of cancer of the bladder, thirteen of central nerve lesion with bladder symptoms, four of prostatic abscess, and eight of bladder papilloma.

This brief summary of cases presenting urinary symptoms characteristic of prostatic change shows that but fifty-two presented a true hypertrophy, four fibrosis, twenty-one carcinoma, and sixty-five were in a class that may advance to hypertrophy or carcinoma. The others were not true prostatic cases. This study of cases under close observation shows first of all the necessity of investigating the earliest urinary symptoms, the establishment of an accurate diagnosis by all our means at hand, and the institution of proper means of treatment.

TREATMENT.

When complete urological examination proves a case to be one of true prostatic hypertrophy, prostatectomy is the operation of choice, and can be carried out in nearly all instances.

The keynote of the situation is the relief of the most distressing symptoms as soon as is consistent with the circumstances. This means drainage of the bladder.

Bladder drainage relieves congestion of the prostate, back pressure upon the kidneys, toxemia resulting from interference with kidney function, and sepsis when infection has taken place. Such a sudden change is not always advisable or safe at once. The slow emptying of the bladder by catheterization, if this is possible, or even an indwelling catheter for

a period of time, may be wise. The patient suffering from prostatic obstruction and the back pressure resulting from it, has developed a certain balance which cannot safely be broken at once. A sudden relief of this pressure may result in suppression of urine from acute congestion of the kidneys.

I would like to cite the case of a man seventy-one years of age, first seen with a bladder which extended well above the umbilicus, and which, by estimate, probably contained sixty ounces of urine. A catheter was passed and retained in position. The bladder was not completely emptied for twelve days, at the end of which time it was emptied every few hours. Even then the patient became uremic, a condition which lasted a week before the symptoms—dry tongue, stupor, loss of appetite, abdominal distention, hiccough, and suppression—disappeared. He was then drained by a suprapubic tube. There was less reaction following this procedure, and after the prostatectomy, ten days later, there was no reaction, the patient was out of bed the following day, the wound was closed a week later, and he left the hospital two weeks after prostatectomy.

The first step in the relief of the prostatic obstruction is suprapubic drainage (under local or gas oxygen anesthesia). There is always a reaction following this step, from the cause mentioned above.

The difference between the reaction after suprapubic drainage and that after catheterization shows that the catheter drainage is not complete. Functional tests by the estimation of blood urea nitrogen content and phenolsulphonaphthalein output are extremely valuable during the period of drainage, to give us the accurate kidney balance. This period of drainage should continue until the patient has struck a new kidney balance at a certain level, which is maintained.

I would like to cite two recent cases. The first was a man seventy-three years of age, who came to me with sixty-two ounces of urine in the bladder, infection of the urinary tract, sepsis, high temperature (105° F.), kidneys that were palpable and tender, poor heart action—in fact, a picture of *extremis*. After catheter drainage for two weeks he was given a suprapubic drainage. This was followed by temporary suppression, but this in turn, by improvement in his general condition, which was continuous. The kidney tests at this time showed blood urea nitrogen sixty-four mils. to the c. c. and the phthalein output was too low to estimate. After three months of drainage, there was marked improvement in his general condition, the blood urea nitrogen reached a level of thirty mils., and the phthalein for two hours, fourteen per cent. He now went through the prostatectomy with no reaction, the wound was closed in ten days, and he is now in excellent condition, although the kidneys are largely destroyed.

Another patient, eighty-nine years of age, went through the same clinical course, his suprapubic drainage lasting three months, the prostatectomy at the end of this time resulting in no reaction, the wound closing in one week.

While these were extreme cases, many others in which I would have hesitated formerly to do a prostatectomy, went through with almost no reaction.

Only one patient, an operative case, of this group died, death occurring from pulmonary embolus twelve days after operation, with the wound healed.

The essential features of the operation are:

1. Suprapubic drainage of the bladder as soon as is justifiable.
2. Maintenance of suprapubic drainage until the patient has reached a new kidney balance, as evidenced by the patient's condition and by special tests. Such drainage relieves congestion of the bladder neck, with shrinkage of the prostate and lessened liability of hemorrhage at prostatectomy. It allows the wound to become a walled off sinus, lined with healthy granulations, and the bladder infection to clear.
3. Prostatectomy—performed through the dilated suprapubic sinus—by intraurethral enucleation, control of hemorrhage by a Pilcher bag.
4. Removal of the bag in twenty-four hours, allowing the suprapubic wound to heal by granulation,

which takes place rapidly owing to the healthy condition of the wound and aided by an indwelling catheter in the urethra.

Prostatectomy performed in this manner in cases of true hypertrophy, by its safety and excellent functional results, has changed the aspect of this dreaded condition, with its far-reaching complications. It is an operation to be considered before serious complications have become manifest and in cases that were formerly thought of as impossible surgical risks.

Too much emphasis cannot be laid upon the necessity of a careful study of cases presenting urinary symptoms, as evidenced by the fact that but fifty-two of 204 cases showed true hypertrophy, and of the proper observation of all cases, bearing in mind the large proportion of cases of carcinoma and our limited means of coping with malignancy in this location.

40 EAST FORTY-FIRST STREET.

Urologic Life Extension

By T. WARSAW WILLIAMS, M. D.,
Milwaukee, Wis.

The incorporation of a Life Extension Institute in New York city, under the auspices of such men as former President Taft, Colonel William C. Gorgas, Professor Irving Fisher, Elmer E. Rittenhouse, Dr. Eugene L. Fisk and many others, is significant of the progressive spirit of the times. Life extension depends largely upon the preservation of virility; I might say almost wholly. Our chief interest in it, as physicians, is the study of the resources offered by the medical sciences for deferring old age by deferring presenility. The physical and mental processes of life are largely dependent upon the reproductive functions and the ability to contribute to the continuance of human life on the globe. Their final extinction, from a physiological viewpoint, indicates the termination of the useful period of life, after which the individual cumbereth the earth, and, as suggested by Osler, might as well be chloroformed.

While the therapeutic plane has been elevated within the last ten years to an extent that renders the textbooks of our college days practically obsolete, no material improvement is noticeable in urologic teachings. This is due, as Dr. Vecki says, to the fact that the subject has never received the attention its preeminent importance deserves. Few medical men can boast ever having had an opportunity to hear a clinical lecture on sexual impotence, and the complaints and criticisms of authors all over show that this state of affairs exists in both Europe and America. Recent indications, however, as he admits, point to a better future, since such men of prominence and learning as Eulenburg, Krafft-Ebing, Furbringer, Martin, Lydston, Block, Sturgis and many others do not think it beneath their dignity to take up the perplexing problems of sexual life. It is a con-

summation to be devoutly hoped for that ere long the conventional medical lies that fill the pages of every book, brochure and article on the subject will disappear.

The light dawning upon urologic conservation is not apparent to the medical eye alone, but also to that of the public, which demands of science the prolongation of virility. What can we do for the sexually dead? If a man die, sexually, shall he live again? Yea, verily. The world is awakening to the possibilities of urologic life extension, i. e., to the retention of physiological potentia virilis as long as the other physical powers. The theory that the vita sexualis contributes immensely to the prolongation of life in general, and that the oncoming of age may be deferred so long as the reproductive functions remain active, is one pretty generally accepted by the foremost medical men of our time. Complete potency, as Dr. Iwan Block (1) says, has been observed in men of seventy and eighty years; and isolated cases have been recorded in which men of ninety and a hundred years have procreated children. The time will soon arrive when these will not be isolated cases. In the sense of Metchnikoff and Hirth, who proclaim the prevention of senility as a hygienic ideal, this physiological potentia senilis is no Utopia, and a future macrobiotic will defer the onset of old age by from ten to twenty years.

Potentia senilis, the retention of youthful vigor beyond the usual age at which most men lose all interest in love and marriage, is now rendered possible, not by any elixir of life or universal panacea, but by the scientific application of well known physiological principles developed from the researches of the older German physiologists—some of whom wrote over seventy-five years ago—includ-

ing Guenther, Hirtl, Eckhard, Lovén, Goltz and others.

The science of medicine should afford humanity that relief which it has failed to give throughout the centuries, and I am happy to say that we at least see a new light in that direction. To get down to the gist of the means at our disposal for restoring and preserving the virile powers, I might as well confess that it is useless to consult the oracles of the world's Delphic temples that have spoken since Hippocrates was born, some 460 B. C. They are not few nor silent, it is true, as an ample catalog of musty tomes attests; but they speak with an uncertain tone. As Dr. Vecki says: "Everywhere in the world it seems to be considered the proper thing to treat the affair with supercilious nonchalance."

If we inquire into the causes of premature decline of the reproductive functions, we are answered with words that mean nothing, "early abuse or later excesses or both"; "overwork," "structural changes," "organic complications," "the natural depreciation of age," etc., words that are only true in a general way, that we knew before, used to cover ignorance of fundamental principles of practice in this form of urologic ailments.

We might ask why these causes do not operate equally upon the other bodily functions—digestion, metabolism, assimilation and nutrition? Our present inquiry refers more particularly to functional sexual incompetence, in which the general physical condition in other respects is comparatively normal.

The ghost of sex weakness that has haunted the pillow of mankind so long has been laid at last. The greatest bugaboo of human ailments, one that has opened a regular Pandora box of suffering, misery and unhappiness, the mainspring of more misery and crime than all other physical ills combined, has at last been stripped of its terrors because science has penetrated its causes and points out a mode of relief.

In fact, there never was any real mystery about impotentia sexualis to excite our special wonder. On the contrary, there is no reason why the functions of sex should not depreciate with the advance of age or gradually fail in unison with other vital functions, or in advance of them. The eyes usually begin to get old at about forty, necessitating the use of glasses and the teeth often give out before that age. The hair also begins to get sprinkled with "silver threads among the gold," and in many the digestive functions become disordered at an even earlier age. The functions of the liver, bowels, kidneys, bladder, prostate gland, etc., from various causes are frequently disordered before fifty or sixty. Biliary insufficiency, intestinal indigestion and auto-intoxication are common ailments and have to be reckoned with before that age. Seventy-five or eighty per cent. of the death roll previous to eighty are preventable and curable conditions if looked after and treated on common sense principles.

It is well known that these conditions may be prevented, or removed, and life prolonged many years, by proper care and treatment. The greatest number of deaths from intercurrent affections that carry off hundreds, thousands and millions of human beings every year, are due to preventable

causes. Most deaths, indeed, that occur previous to eighty years, are premature. When we look over populous cemeteries, it is a saddening reflection that the majority of those silent sleepers might have lived ten, twenty, thirty, forty, fifty or more years longer had they, or their physicians, known what should be done to escape premature decay and death.

The sex functions provided by an Allwise Creator, for the continuance of life on the globe, are the very last of the vital functions to be developed. As a rule they do not begin to sprout, upon an average, until after all the other functions have been in operation for from twelve to fourteen years. Logically, therefore they should be the last instead of the first to fail, and in any case, should remain active at least as long as the other physical functions. Why don't they do it? The answer to this question is that all the other vital functions are more or less abused until their ability to functionate is impaired. This is the case with the eyes, teeth and digestive apparatus, as well as the sex functions.

It is a well known physiological law, that too frequent or too powerful excitation of a nerve, exhausts its power of reacting to that particular excitant for the time being. It must have time to rest and recuperate, after which it will again respond. If forced to respond too frequently, with insufficient rests between, its excitability is first reduced and finally exhausted. This is what is meant by sexual excesses,—too frequent excitation of the nerve-centres, and insufficient periods of inactivity between, until their power of reaction is suspended or annihilated. Evidently then, when an individual in the prime of life, normal in other respects, complains of impotentia sexualis, we are justified in informing him that he has simply exhausted his capacity for the time being; but that it is not dead; it may be revived by rest, moderate use, and special restoratives.

Abuse of any function does not mean misuse, or excessive use. On the contrary the nonuse of any function, organ or part, is more destructive than its excessive employment, hence undue continence is a moral as well as a physical evil. Man is supposed to use the faculties that mother Nature and father God gave him. Nothing was made in vain. Why should men and women have been given a purposeless, useless function or organ, and be told to go forth and increase and multiply?

Physiology emphasizes this fact in an unerring manner. If we do not employ an organ or function, Nature treats it as a useless appendage and proceeds to destroy it by starvation. "Why, indeed," she asks, "should I bring precious blood-bearing nutrition for growth, development and functional activity to an idle organ?" So she transfers it to muscles, bones, and tissues that work and must be sustained. Note what she did to that thymus gland when it stopped functioning. The organ that does not work, dies—literally starved. It does not get its quota of nutrition, has to live on itself, until it atrophies and fades away. Nutrition and work go together. If a muscle works, it demands nutrition—and gets it promptly. Nature never neglects her workers. The more work it does, the more nutrition it gets, and the more nutrition it receives,

the bigger and stronger it becomes. It is begging the question to say that the sex organs are anomalous in this respect—that they maintain their vitality just as perfectly as when working overtime. It is simply a physiological lie. Nature never made one law for a muscle and a different one for a gland. She never made a gland to remain fallow and still retain its functional power; if a muscle remains inert too long, it wastes to a mere thread. Ceaseless activity is the price of vitality. Hold your arm above your head, like the Eastern fakir, long enough, and nothing will be left but the skin and bone. Hold the head of the penis down long enough, and it shrinks away.

Those who preach and practise such logic, after they have wasted their manhood, come to me, sometimes, and ask for a remedy for the condition. But although the blood can work wonders in restoring and rebuilding injured and wasted tissue, there is nothing about dried skin and inanimate gristle to hang the flower of virility upon.

There is only one way under heaven whereby virility can be restored, and weak men made virile and that is flushing the anemic organs with an abundance of red blood. The question is, how can we do it? How can we create an increased circulation in the genitalia? I have no new, untried discovery to offer for the purpose, but have found the old ones effective if properly used.

Parts that have depreciated on account of loss of blood, starved as it were, can be restored by an increased blood supply. Physiologists understand this fact, and tell us that the nutrition, strength, development and functional activity of an organ or muscle depends upon the quantity of blood traversing it. If the amount is too small, the structure will be diminutive, and the part will atrophy. The athletes of ancient Greece and Rome secured superdevelopment of the muscles by a rigid system of exercise which brought a larger quantity of pabulum to the parts.

It would be illogical to assert that the rule did not apply to the organs of sex, as all experience proves the contrary. True, an athlete may be and often is, partially impotent. So are many priests who under their vows dispense with carnal pleasures. The priest becomes emasculated by the non-employment of the sex function. The athlete may be equally so, despite the fact that he is otherwise robust and powerful. But he understands that exercising the deltoid and feeding it several times the value of blood that uncultivated deltoids receive, will not develop or strengthen his sex organs any more than the muscles of the legs. For this reason, it is a fact well known to practical men that nearly all athletes are impotent.

In the treatment of sex weakness, we come in contact with the hoary error of the popular idea, shared to some extent by medical men, that a remedy for impotence is some sort of aphrodisiac that restores erectile powers as by magic, "while you wait." But if we are asked how, or upon what physiological principle such a restorer is supposed to act, we are compelled to answer that there really is no such thing as an aphrodisiac or special restorer of virility known to medical science, as the late Dr.

Hammond said, although there are agents, like yohimbin, cocaine, opium, cannabis indica, etc., that exert an indirect influence in giving temporary "pep" to the generative organs, either by suppressing the inhibitive centre, or stimulating the spermatic and ovarian plexuses, or perhaps both. But in such cases, stimuli of this nature, while producing a sporadic reaction, eventually render the impotence more profound, as the nerves soon cease to respond.

Not to waste time on the usual methods, the usual routine embracing local treatment, consisting of cauterization of the ejaculatory ducts, argyrol or other silver injections if prostatitis is present, Winternitz psychophores or cooling urethral and rectal sounds, injections of cold water into the urethra, sitz baths, river and lake bathing, matutinal applications of cold water, massage of the orchitic glands as recommended by Abrams, etc. These are all good things, in their way, and should not be neglected, in conjunction with the specific treatment. Their principle of action (not understood in many instances by those employing them) is the production of hyperemia sexualis, by reaction. But it is too slow and tedious to be depended upon, and does not produce sufficient reaction. The usual internal treatment is almost anything the physician's fancy may dictate—perhaps some of the much vaunted aphrodisiacs, yohimbin, or cocaine, the action of which is very similar, cannabis indica, opium, quinine, etc. All these drugs are given empirically, because they have been recommended as aphrodisiacs, without any clear understanding of their principle of action which is (or should be) stimulation of the genitospinal plexus. Favorable results may sometimes be obtained by these means, but as a rule they are uncertain, unsatisfactory, and disappointing. Very little permanent benefit can be expected from them, except to entertain and buoy up the patient for a while, and enable the doctor to enter something upon his ledger. But upon the whole, the final result in all cases, so far as my experience goes, is that little or no relief for marital incompetence can be expected from these measures. They do not produce active hyperemia sexualis, increased circulation, nutrition and functional activity of the organs, without which no actual improvement of the condition is possible.

If we specialize along this line, something more is expected of us than of the family physician, who only temporizes. In fact, the urgent necessity of getting results by the specialist renders a remedy that "cures quickly, safely and pleasantly" a *sine qua non*. In other words, we must bring about functional changes that will enable the impuissant patient to perform his rôle in the great drama of life in a manner creditable to the attributes of his sex.

All the processes of animated nature on the globe exist by the contraction and dilatation of the little bundles of nerves called plexuses. They are referred to in a general way as nerve centres, from which radiate the nerve branches and filaments innervating the various organs and tissues of the body.

According to a law of the economy, the stimulation of a certain plexus will produce contraction

of the ganglionic centre, and the muscular tissues and arteries which it supplies, reducing the quantity of blood reaching the organs or tissues supplied by the arteries; tickling another centre produces the reverse effect: relaxation, and an excess of blood supply of the parts supplied. Stimulation of the third, fourth and fifth cervical, for instance, produced by percussion, the rapid sinusoidal current, or hormones from the ductless glands, acts upon the phrenic nerve and contracts the lungs and bronchial tubes. A similar reflex action is produced by applying stimuli to the seventh cervical, causing contraction of the liver, spleen, heart, aorta, stomach, pancreas and arteries; it is resorted to for decreasing the blood supply of the lungs in congestion, as in pneumonia, for instance.

Percussion produces the vibrations upon which the therapeutic effects depend. The interrupted sinusoidal current is better than percussion, because the vibrations are shorter and more rapid. The electric current has nothing to do with it, as the vibrations produced by a vibrator, similar to that used by barbers, but smaller, produce the same effects. Rapid vibrations over the seventh cervical will relieve asthma and enable the patient to take a deep breath in one minute. A vibrator applied over the first, second and third cervical is one of our best remedies for the dizziness and vertigo of elderly people in whose brains sclerosis of the small arteries has already commenced. I have in several instances reduced that form of fibrosclerosis of the penis to which curvature upward or sidewise, is due, by vibratory massage. Should trials of this method establish its efficacy in this condition, so common in advanced life, its simplicity, and the fact that it involves no medication, will commend it equally to the public and the profession. Vibratory treatment is also valuable in deafness, lumbago, neuralgia and muscular rheumatism. Just how it does it, I do not pretend to know, but deaf people who work in factories, where there are vibratory noises, soon notice an improvement in their hearing.

Reflex dilatation of the abdominal arteries, stomach, spleen, liver, intestines, uterus, ovaries, etc., is caused by rapid vibrations over the tenth, eleventh and twelfth dorsal vertebræ. The prostate gland is contracted by vibrations, (percussion, electrical or vibration) over the twelfth dorsal—a valuable resource in prostatic affections.

The recognized fact that the quantity of blood traversing an organ can be increased or diminished at will, and its nutrition, development and functional activity modified, increased or diminished, by electrical and mechanical means, or by reacting upon its nerve centre, gives us a clue to the treatment for impaired sexuality. In this condition we usually find poor circulation in the organs supplied by the inguinal arteries. The organs themselves are often found to be in a relaxed, frigid, unexcitable condition, and in those who have not cultivated their sexuality, they are small and undeveloped. The condition in men, and women, too, for it is no respecter of sex, of sixty or sixty-five, is often associated with high blood pressure. The inguinal arteries consequently are more or less contracted, so that the blood supply of the organs is materially diminished.

When erection and libido occur, the blood pressure in the arteries generally, particularly in the inguinal, drops from fifteen to thirty degrees; they expand and convey an increased supply of blood to the erectile tissues, which become turgescient. If the general blood pressure is abnormally high, the arteries are contracted and do not expand sufficiently to supply the additional circulation required to produce the phenomena of erection. Remedies which lower the blood pressure are therefore necessary in the treatment of such cases, but should act directly upon the *centrum genitospinale*.

I have found that several of the hormones, especially those of the orchitic, prostatic and thyroid glands, stimulate the sex centre almost instantaneously, causing it to dilate, producing a similar effect upon the arteries of the genitalia, increasing the flow of blood into the sex organs. Their effects may be increased by combining them with pressure depressants, such as the nitrite group.

The use of these combinations internally, however, is not very satisfactory nor commendable on account of the action upon the heart and their systemic effects generally. After much experimentation I arrived at a less objectionable method of administration, viz., by securing their direct action upon the genitospinal centre through the medium of the *nervi erigentes* of Eckhard. I found that this could be readily accomplished by the injection of a well balanced combination of the hormones referred to into the anterior urethra of the male, or applying it externally to the *membrana preputialis* of the male, or to the glans clitoridis and the membranes of the labia of the female, where it almost instantly induces turgescence of the erectile tissues accompanied by libido. I found, by actual tests, that within a few minutes after applying these agents that the blood pressure in the inguinal arteries dropped from fifteen to twenty degrees, followed by more or less turgescence of the organs and a tendency to erection.

I first made these experiments upon the assumption that Goltz and Lovén were right in the belief, as stated by the former, that there was some sort of connection of the pudic nerves of the penis with the *nervi erigentes* similar to that of the vagus with the heart, or the chorda tympani with the vessels of the glandula submaxilaris; I demonstrated experimentally that Goltz and Lovén were right, and that impressions made upon the terminal filaments of the *nervus pudendus* (which supplies the prepuce and urethra in both sexes) react upon the genitospinal centre within a few minutes. All that is necessary to set in motion the train of phenomena which causes normal erection is to apply the proper medication to the inner lining of the prepuce or the urethra. The effect is not due to stimulation or varicosity of the membranes, as the agent used may be as bland as cream, but to a physiological impression reflexed to the centre.

These facts and experiments open the way to a better understanding of the basic principles of a new method of treatment to restore and preserve virility. Sexuality, like the muscles and all the other physical powers, can only be revived, strengthened and developed by cultivation. There is absolutely no other way. The disuse or misuse of any organ leads in-

evitably to its rapid deterioration. All the balsams of the Orient and the Occident can never recuperate, upbuild and strengthen them without the proper, moderate normal exercise of their functions, which increases the circulation in them. Enforced continence is an ascetic crime against nature; it is the mother of degeneration of the species. You might as well suspend an arm in a sling and expect it to remain strong or become muscular as to expect the sexual organs to retain virile vigor while their functions are suspended. It is a contradiction of terms.

The sacrohypogastric plexus (they are substantially one) presides over the genitourinary functions, and it is through those centres that we reach those organs by specific treatment. The object of the orthodox treatment of sexual impotence is to produce hyperemia sexualis, an increased blood supply. The easiest, I might say the only, effective way of doing this is by stimulating the genitospinal centre. Stimulation of that centre, by the God given stimulus of sex or by any approved internal or external agent, which increases the blood supply of the generative organs and induces hyperemia in them, is based upon a physiological anomaly met with only in the circulation of the erectile tissues which is not generally understood. Ordinarily, stimulation of a nerve causes it to shrink and contract, reducing the calibre of its arteries and the amount of blood it can carry. The reverse is true as far as the circulation of the erectile tissues is concerned. Stimulation of the genitospinal centre dilates instead of contracting the arteries and arterioles of the genitalia and causes a material drop in the blood pressure of the arteries supplying the generative organs, such as occurs in normal erection (Carpenter).

Erection of the intromittent organ as we know, is caused by an increased afflux of arterial blood and a retarded outflow of venous blood. Erection cannot, however, as Vecki (2) remarks, be brought about by mere compression or ligation of the veins. "That an increased flow of arterial blood takes place is proved by the lowering of the blood pressure in the neighboring inguinal arteries, and even as far as the arteria cruralis, as shown by the manometer. How this increased arterial afflux is caused is not yet explained." Hyperemia of the sexual organs is caused by excitation of the erection centre by either mental or physical causes.

The fact, as stated by Vecki, that mere compression or ligation of the veins will not produce erection, explains the fallacy of the various devices for procuring erection based upon this principle. There must be an increased afflux as well as a diminished efflux. We frequently meet with cases in which the afflux would be sufficient for erection if the blood could be retained in the erectile tissues instead of returning as fast as it enters. But, as a rule, there is more or less anemia of the generative organs from deficient circulation, and they are cold and clammy.

This condition is principally met with in elderly men and younger ones who have been too active in cultivating their sexuality. It is due, as a rule, to varicosity of the trabeculae of the corpora cavernosa. These cases call for a mixed treatment, something to excite the influx of blood into the organs and something to retard its outflow.

In these cases it is not sufficient to increase the circulation in the parts. In addition we must apply an obturator of some kind to compress the veins just sufficiently to prevent the too speedy return of the blood so as to retain the erection. These obturators can be made of different patterns. Some are merely wide rubber bands with an elastic retaining strap or cord that passes under the scrotum and prevents the appliance from slipping off, and is not in the way. These are better adapted for cases of partial impotency. In more pronounced cases, more satisfactory results are obtainable from an appliance of unvulcanized and vulcanized rubber worn under the everted prepuce, where it is invisible. Mechano-therapeutics is properly employed in these cases on the same principle as artificial teeth and limbs and eyeglasses.

In my private practice during the last twenty years I have adopted this treatment in several thousands of cases, and through its instrumentality have been able to extend the period of virility in many of them from ten to twenty years, most of which otherwise, must inevitably have been down and out years ago.

That life is prolonged by keeping the genitourinary organs in a normal condition is a selfevident proposition. Decadence of any one of the organs may be compared to removing one of a row of bricks which causes the rest to fall. Most men are really potent up to seventy or eighty; but owing to various causes, principally loss of erectile power, are unable to exercise the sex functions, and perforce are obliged to discontinue sexual relations with their wives. In most of these cases, libido and physical vigor are practically unimpaired, but loss of erectility prevents exercise of the sex function.

As age creeps upon man, like a thief in the night, it first impairs and finally destroys the ability of the obturator and constrictor muscles concerned in erection from performing their office or compressing the corpora cavernosa and deeper veins of the penis and thus preventing the return of the blood as fast as it enters the organs. The trabeculae of the corpora cavernosa also undergo structural changes, the ducts become flabby and patulous, rendering their closure more difficult.

The remedy in such cases is the use of something which accelerates the entrance of the blood, such as I have previously referred to as hormone compounds, and an artificial obturator which will slightly compress the corpora cavernosa and the dorsal vein sufficient to prevent the too precipitant outflow of the blood without disturbing the urethral canal.

The artificial obturators previously referred to in this paper should be adapted to each individual case, no one form being suited to all cases. When properly constructed, they have, in my experience, and in connection with appropriate medical treatment, extended virility in many cases for several years. Some patients for whom they were prescribed as far back as 1900, although now from eighty to eighty-five years of age, possess the ability to cohabit with their spouses. A gentleman residing in Kenosha, Wisconsin, who adopted this method of treatment ten years ago, recently married, at eighty-six.

Middleaged and elderly men who do not wish to relapse into innocuous desuetude, so to speak, should, in my opinion, keep alive the vital spark of virility as long as possible. In this connection a remark of George Hirth (3) is worthy of quotation.

"I do not ask," he says, "that the man in advanced age should play with his sexual powers; but that he should possess the consciousness of being able to use them—that I demand."

As previously remarked, sexuality is a cultivatable physical quality, and it should be cultivated. Cultivation not only promotes sexuality, but increases the development of the organs. As a rule, those who have abnormally small penes, have not much sexuality. This creates a vicious circle. Lack of sexuality disinclines them to cultivate it, and its noncultivation retards the development of the organs. When any glandular organ ceases to functionate, and no longer fulfills the purpose for which Nature intended it, she seeks to eliminate it by starving it out, by failing to supply it with blood. The sexual glands are no exception to this rule. When the sexual functions cease to be employed for the legitimate purpose for which they are intended, they invariably decay—or waste away. The remedy for this condition, often unintentionally permitted to develop, is to reverse the process and exercise their functions. The blood supply of a part is proportionate to the demands upon it. Nature is immediately aware of the demands being made upon the part and hastens to supply blood to reinforce and strengthen the parts to meet the demand. Thus, when increased demands for work are made upon the heart muscles, compensatory hypertrophy takes place. Upon the same principle, in proportion as an increased demand is made upon the sexual powers, Nature establishes compensatory development. The physician logically seeks to aid her by stimulation of the nerve centres controlling the nerve and blood supply of the parts. This practice has succeeded in men of over fifty or sixty, but succeeds better between the ages of thirty and forty, and still more so in the constructive period previous to thirty.

For the modern treatment of sexual debility in man, I have no universal panacea, nor even a new elixir vita to offer. As Dr. Sajous says, "the great need of the times is not so much new remedies as the judicious use of the old and tried ones with which we have been familiar for fifty years or more." Although we have no cureall, the treatment I have employed in my clinical practice in more than ten thousand cases, since 1890, has proved curative, or substantially beneficial in about eighty per cent. of the cases as they presented themselves. Of the remaining twenty per cent., some were incurable, from structural organic changes or other causes; others were of a psychic nature which no medicine could reach, but the large majority of failures were due to the habits and mental attitude of the patients themselves, inability or indisposition to carry out instructions. The treatment itself is easy and simple, but no matter what class of ailments are treated in dispensary and private practice, nor what manner of treatment is employed, there will always be a certain contingent that you cannot

materially help, owing to idiosyncrasies inherent in the patients treated, regardless of the merits or demerits of the kind of treatment employed.

The basic principle of the method of treatment I have found most satisfactory, that has given the best results in the usual forms of sexual debility—is the induction of active hyperemia sexualis by regular moderate stimulation of the genitospinal centre, flushing the organs with blood, increasing their circulation, innervation, nutrition and functional activity.

The experimental researches of some of the older German physiologists, especially Guenther, Hirtl, Lovén, Eckhard, Budge, Goltz and others, gave me the first inkling of this theory of treatment. Guenther's experiments on stallions, nearly eighty years ago, confirmed later by those of Eckhard, and others, proving excitation of the *nervus pudendus* of the prepuce, capable of causing erections, are particularly suggestive. Although neither Guenther himself, nor the physiologists of his day, seemed to be aware of the significance of his discovery, he builded wiser than he knew. It was in following out the logical inferences deducible from it that suggested to me the clinical experiments which finally led up to what may be truly called the modern treatment of sexual debility in man. It does not consist of any special specific aphrodisiac to be taken inwardly or injected, nothing that will, presto, change! clothe the aged and impotent with the *toga virilis*, like the baptism of fire administered by Mephistopheles to Faust, changing them instantly into vigorous, young men. True, it really is miraculous in the sense that it transforms, so to speak, premature senility into virile old age, "wintry, but kindly," setting back the dial as it were, from ten to twenty years; but it is one of those miracles of science which often happen these days, more logical, if not as so supernatural, as the miracles one reads about in ancient history. But it is a gradual change from impuissance to a normal condition of the reproductive functions, a steady, continuous recuperation and building up process due to improved circulation in the organs, effected by periodical stimulations and rests of the sex centre. It keeps men young, young looking, young feeling, young acting.

As previously remarked, the various substances capable of stimulating the genitospinal plexus, when taken internally—cocaine, yohimbin, cannabis indica and opium—although they produce an unwonted stimulation at first, the ganglion soon ceases to respond, and the last state of that patient is worse than the first. One reason is that it is necessary to take these stimulants in large doses in order to affect the centre; the mingling of the ordinary dose with the thirteen pounds or more of blood in the body being insufficient to affect the nerve centre materially; the latter becomes accustomed to the stimulus and ceases to respond. Poisonous doses speedily paralyze it and the patient is bereft of what little virility he had left.

There are, however, benign, harmless stimulants of the genitospinal centre which, when administered in minute doses to the genitospinal centre direct, act as a vital stimulus. The best of these are the nat-

ural hormones, or active principles secreted by some of the ductless glands—the orchitic, prostatic, ovarian and thyroid, lecithin from cord and brain substance. The action of some of the internal secretions, the suprarenal and pituitary, for instance, is quite different. What I have found most satisfactory for the purpose is an organic compound of the extractives first named, in a seven per cent. alcoholic normal solution, with the addition of antiseptics and a small flavoring of the nitrites in the form of a sterile, antiseptic, permanent emulsion, suitable for urethral injection.

This organic compound is administered *per urethram*, once a day as a rule; in anticipation of coitus, the patient may make an extra application. The average dose is a cubic centimetre or an ordinary medicine dropper or pipette half full. It is injected into the urethra with a bulb pointed pipette, retained for from one half to one minute, and the overflow is applied over the glans and everted prepuce. There is a slight twinge when it is first injected, but no irritation of the urethra, followed by slight frontal headache and flushing of the face for a few minutes. After the lapse of five minutes or less, the veins of the sexual organs begin to fill up, and the organ becomes more or less turgescient. This depends upon the degree of anemia and weakness present, being less marked in weakened conditions of the organs. Its aphrodisiac effects usually last one or two hours, gradually subsiding.

It is not necessary, as a rule, to use it oftener than once a day. It is a well known physiological law that, if a nerve is excited too frequently, it will cease to respond to that particular stimulus. Consequently, when applied too frequently, or in overdoses, it ceases to evoke the reflexes of the sex centre, thus rendering it impossible to abuse its use by keeping the organs in a continuous state of erethism. This quality thus adds to its medical excellence in premature emission in coitus, and spermatorrhea with involuntary seminal losses. In these cases it may be used twice a day. At first, of course, hypogastric stimulation aggravates the symptoms; but if it is continued for ten to fifteen days, the parts lose some of their irritability and the chronic erethism, due to hyperesthesia of the prostate and spinal centre, is gradually overcome.

The physiological explanation of how such a medicament applied to the urethra and prepuce stimulates the genitospinal centre, is as follows:

Guenther's experiments on animals in 1836-37, subsequently confirmed by Eckhard, proved that excitation of the prepuce gave rise to the phenomena of erection. Goltz's explanation was that connection of the *nervi erigentes* (which are mere filaments from the hypogastric plexus), with the *nervus pudendus* of the penis, is similar to that of the vagus with the heart and the chorda tympani with the vessels of the glandula submaxillaris. Whether this is true or not, it has been clinically demonstrated that some such nervous connection between the *nervus pudendus* and sacrohypogastric plexus exist, as shown by the fact that certain stimuli applied to those membranes produce the usual phenomena accompanying stimulation of the genitospinal plexus—dilatation of the arteries, lowering of

the blood pressure in the pelvic arteries and hyperemia sexualis, in less time than it has taken to describe it. This fact enables us to flush the genitalia with blood and produce hyperemia sexualis at will.

I should not omit to mention in this connection that the action of the emulsified preparation on the female organism is as prompt and efficient as upon the male. A valuable adjunct in retarded sexuality, chlorosis, anemia and amenorrhea, and in so-called idiopathic frigidity or original absence of the sex instinct, from anemia and atonic conditions of the spermatic and ovarian centres.

Flushing the genitalia daily with warm, red blood, producing periodical active hyperemia, gradually reestablishes the normal circulation, increases nutrition, sexual development and functional activity, and in time restores normal potency. It is a good thing for any old man to do this three or four times every week; a sense of sexual preparedness makes him feel younger and creates an interest in life, whether he cares about exercising his sexuality or not. Improvement of sexuality is usually noticeable in the course of a month or so—oftener in much less time; in other cases it is the work of several months; all depends upon the case; many of the patients get discouraged if they do not feel like twenty-one after using it a few weeks. As a rule, within a few months material beneficial results will reward faithful persistence in the treatment. Reference is here made to purely functional debility, without structural organic complications. These are almost always present, in the shape of prostatic troubles, frequent urination, dribbling of urine, inability to hold the water long, getting up nights, etc., due to prostatitis and hypertrophy, in those between fifty-five and seventy. I cannot discuss these cases now; it would take a chapter to do so. These form by far the larger proportion of cases of sexual impotence met with in genitourinary practice, and it is evident that these causal complications must be ameliorated or removed before we can reasonably expect to accomplish much in the way of restoring virility. In fact, after the removal of the causal complication, the improvement of the circulation speedily revitalizes and invigorates the organs.

I am in accord with Dr. Morrow (4) that the exercise of the sexual organs within due limits, has the effect of strengthening, invigorating and preserving them in their full integrity, while the opposite condition is produced by undue continence; and with Dr. Vecki, that in many cases treated, or rather maltreated, by all kinds of local applications, milked, massaged and bruised, they would receive much more benefit from regular sexual intercourse. The vesiculæ seminales, the prostate and neighboring glands, as he points out, are oftentimes clogged with the products of their own secretions, the result of which is passive hyperemia and its consequences. In all cases in which a physician might massage the prostate and milk the seminal vesicles, you may safely order regular sexual intercourse, the natural way of emptying these glands of their secretions.

But the trouble in these cases is that it is in this

very condition that the patient is partially or wholly physically incapacitated by loss of erection for taking this advice. The employment of the crippled function is as essential as the passive exercise of a crippled arm or leg. In these cases, a mechanical appliance, or obturator, for supporting the intro-mittent organ at its base, and supplementing the erector muscles of the penis in their efforts to close the openings through which the blood returns as fast as it enters the organ, is a *sine qua non*. It must be constructed so as to produce no structural injury, such as undue closure of the urethra, thus arresting the ejaculation of the semen, which has been one great objection to most devices proposed for the purpose. Impotence, due to paralysis, atrophy, or decay of the posterior columns, in which there is absolutely no motive power to graft upon, are necessarily hopeless.

If an appliance is used, due care must be exercised that while it exerts sufficient pressure on the corpora cavernosa and the vena dorsalis—not to arrest entirely, but to diminish the outflow of blood, it must in no case compress the urethra sufficiently

to interfere with the free ejaculation of the semen, as the reflux of the discharge against the prostate speedily kindles an acute form of prostatitis, accompanied by hematuria.

Treating Syphilitics*

By LEO L. MICHEL, M. D.,
New York,

and

HERMAN GOODMAN, B. S., M. D.,
New York.

INTRODUCTION.

This paper has been named Treating Syphilitics rather than the Treatment of Syphilis because it has appeared to us that one of the great difficulties today in the therapy of syphilis is that the patient is almost, if not entirely, forgotten. Routine schema are proposed, ideal courses are advanced, injection rules are laid down, and the physician takes his choice by lack of familiarity with all, or by preference to the combination of six, or of seven, or of twelve, or whatever numerical formula appeals to him for the moment.

DRUGS.

In this communication and at this place we limit ourselves to the specific drugs, or those found or designed to combat the causative agent, the *Spirocheta pallida*. The mercurial preparations—and, historically, mercury is the earliest antisymphilitic—may be indicated as those for external application, for oral administration, for intramuscular injection, and for intravenous introduction.

In 1910, Ehrlich introduced to the medical world the results of his experiments to produce a drug having the greatest poisonous action on the cause of syphilis, and yet, at the same time, having almost no harmful effects on the living tissues of the patient. This drug was salvarsan, a synthetic arsenic compound, officially known in this country as arsphen-

amine. Within a short time after its introduction the results of the use of the drug in every possible manifestation of syphilis proved that a specific had been found. Although Ehrlich's idea that one dose of salvarsan would sterilize the patient has not been sustained, the drug today is our standby in the treatment of syphilitics. Ehrlich did not stop with 606, but proceeded with his experiments until 914, or neosalvarsan (neorsphenamine) had been produced.

Just prior to his death, Ehrlich produced a newer drug called sodium salvarsan (sodium arsphenamine), which combined the good features of 606 and 914.

In 1918, Kolle, who succeeded Ehrlich, produced silver salvarsan (silver arsphenamine), which had been suggested by Ehrlich. The rationale of the combination is the reduction of the arsenic dosage by the introduction of the silver component. The preparation is said to be twice if not three times as potent as old arsphenamine. According to Kolle, the ratio of *dosis curativa* to *dosis tolerata* is one to thirty. Solutions of the drug lead to a neutral reaction of the fluid, which is less oxidizable than neo compounds, but, if oxidized, preparations of silver arsphenamine are toxic. The natural color of the solution is brownish. In very dilute solution there is also a suggestion of red. Some men have found the color a disadvantage because they have been unable to judge if the solution were proper or

*Read at a stated meeting of the Clinical Society of the Hospital for Joint Diseases, April 12, 1921.

not, and also because the technic of using a syringe and telling if the needle were properly introduced into the vein by withdrawing some blood is not feasible. Neither of these objections appears to be valid.

The solution of silver arsphenamine should be made with about twenty c. c. of freshly distilled water, or four tenths per cent. saline to the decigram, and in the cold. Agitation is not advised. The fluid may be filtered. The injections should be carefully given, and the drug slowly administered. The doses vary from one tenth to three tenths gram, and few men have advised larger doses, although it has been suggested. The interval between doses has been from twenty-four hours to four or five days. The number of doses given has also varied from six to sixteen, and the number of courses has depended on the stage of the disease, and the reaction therapeutically.

Byeffects and illeffects of silver arsphenamine have been dilated upon by various writers. The angioneurotic symptom complex is supposed to be seen with greater severity than following other forms of arsphenamine. Rise in temperature has been reported. Icterus and exanthem have also been reported, and several isolated grave cases of the same. Bona fide agyria has never been reported.

As the result of an extremely short personal experience (1) and study of the literature, it seems that silver arsphenamine will be a popular drug that will ultimately find a niche in the treatment of syphilis.

We digress here to speak of a nonspirochetocidal but valuable drug in syphilis. Potassium iodide was first recommended in the treatment of syphilis about 1834 by Wallace. Jobling and Peterson have recently explained the action of the iodides as follows: The softening and removal of caseous necrotic material from a gumma is due to tryptic ferment. The gumma, however, persists and remains firm because it contains large quantities of antitryptic substances which are of lipoid nature, being combinations of unsaturated fatty acids. Their power of antagonizing the ferment depends upon their saturation, which in turn can, as is well known, be satisfied by iodine, this forming the well known index used in estimating unsaturated fatty acids. Administration of iodine by saturating the antitryptic substances destroys their power over the tryptic ferments, which then dissolve the caseous material.

These, then, are the trinity of the modern drugs at our command for the treatment of the syphilitic, and it is a judicious use of one or more than one of these in order, or in combination, that makes for the treatment of syphilis. The patient requires more than this, however, and considerations of living conditions, working hours, mental attitude toward the disease, social and marital obligations, have to be fully investigated and properly settled. The matters of food, drink (especially spirituous liquors), and smoking should be mentioned, and directions or prohibitions given as the exigencies of the individual case demands.

It should certainly not be taken for granted that the patient who is a known syphilitic has only syphilis to contend with. A complete physical, neu-

rological, including ophthalmic, urinary and serological examination should be made. The mistake of accepting a positive Wassermann test as proof of syphilis, and therefore without further clinical confirmation diagnosing a presenting symptom as syphilitic, should not be made. Although a report of four plus Wassermann from a reliable and painstaking laboratory undoubtedly means that the patient has or has had active syphilis, many persons who give a positive Wassermann reaction may also have some other disease. This is important to keep in mind in cases of new growth which may be clinically difficult to diagnose. The positive serological finding may prove a deciding factor for the physician to initiate antisyphilitic treatment, and much time may be lost before the true character of the lesion or symptom is recognized and the proper therapy instituted.

PROPHYLACTIC TREATMENT.

We have recently published (2) our observations and abstracts from the literature on the prophylactic treatment of syphilis with arsphenamine. Although Metchnikoff's method of local application of mercurial salve is a recognized effective method if properly done within one hour after the *Spirocheta pallida* has been passed to the healthy person, it is not so well recognized that the injection of arsphenamine in proper doses and at proper intervals is a certain prophylaxis against the disease, even if the injections are begun as late as perhaps three days after the contamination and possible infection. We quote from the summary of our paper: ". . . The injections of arsphenamine in small doses in persons who present no lesions, and who are definitely known to have been exposed to syphilitic infection, has in all the cases resulted successfully in acting as a prophylactic measure. The time since exposure has little bearing on the result, but must be taken into consideration when the minutæ of the procedure are under consideration. In two reported cases, a single injection has been held to be ample. In a patient under our own care, we intend to use a modification of the abortive cure, although she presents no lesions, because the date of the first exposure is longer than the usual incubation time of syphilis." As far as we are able to ascertain there are no reports of the failure of arsphenamine to prevent syphilis when injected during the incubation time of the disease.

ABORTIVE TREATMENT.

Every penile lesion and any suspicious extragenital sore is examined for *Spirocheta pallida*. The primary lesion of syphilis may simulate any and every variety of nonspecific sore. We use as routine the dark field method of demonstrating the *Spirocheta pallida* (3). The demonstration of the organism is proof of syphilis, and treatment with arsphenamine is instituted at once and adhered to in order to eradicate the disease. The period prior to the wide diffusion of the syphilitic organisms—that is, the period of the chancre, negative Wassermann, and no evidence of secondary symptoms—is the primary stage of the disease. This stage is most successfully attacked with intravenous arsphenamine in otherwise healthy persons by the intensive treatment. The intensive method (4 and 5) as used by

us consists of the daily administration intravenously of arsphenamine for three doses. The dose is one decigram for each thirty pounds of body weight, dissolved in freshly distilled and boiled water, neutralized with sodium hydroxide.

We have also used the modified intensive treatment, where it has seemed desirable not to force treatment, and have given arsphenamine on every second day. The clinical results were astounding. Syphilitic lesions disappeared within a few days, and the patients were no longer a menace to themselves or to others. Although we are not willing to let the patient's future rest with the single three day-three dose or a modification of that method, we are certain that in most if not all early initial lesions such an intensive course is sufficient to rid the patient of his infection. All of our cases, however, receive a second course about six weeks after the first.

The serological and clinical results have been exceedingly gratifying with this mode of treatment. No case has clinically advanced from the primary to the secondary stage, nor has there been any suggestion of a positive Wassermann.

Although we have had no personal experience with the following, we have considered injecting three doses of arsphenamine in selected cases of early syphilis within a period of twenty-four hours. This method has been proposed by Scholtz. He states that such a course is sufficient without further treatment. We would not rely on it alone.

SILENT GENERALIZATION STAGE.

The phase of syphilis next advanced from the primary stage is one to which we have appended silent generalization stage (6). The chancre is present, there are no clinical skin or mucous membrane lesions, yet the Wassermann is strongly positive. It has been our observation that the draining lymph nodes are enlarged in this period. The spirochetes are free in the blood stream, but no metastatic distant foci have had time to make themselves evident clinically. Patients who are in this group are given the intensive course of arsphenamine, repeated two or three times, or, if the patient shows no ill effects from the injections, a course of six or even more intravenous arsphenamine injections may be given in one series, one injection every other day. The urine is carefully watched for any disturbance, and of course evidence of disease of the urinary apparatus is a contraindication for intensive therapy. Whether to give mercury concomitantly with the arsphenamine in this stage, or to wait until the cessation of the course, is still a problem; but we have considered that the body has enough to do with the elimination of the arsenic, and the internal rearrangements due to the disease, and we have not thought it wise to add another poison to the system, namely, mercury.

CLINICAL GENERALIZATION STAGE.

In the secondary stage of syphilis the spirochetes have found lodgement in all the tissues of the body, and the defensive perivascular and perilymphatic infiltration of the host may prevent their immediate destruction in every location, even by antisiphilitic medication. Once a syphilitic, always a syphilitic,

does not hold true in the primary stage of the disease, but a certain percentage of secondary syphilitics, especially those who evidence severe cerebral symptoms in the secondary period of the disease, may never overcome their infection, in spite of therapy.

According to the physical appearance of the patient and the nature of the functions of his excretory organs, vascular apparatus, and other systems, we decide the method of treatment to be instituted. Often, especially if it appears to us that the patient is being overcome by his infection, we delay arsphenamine injections until after the injection of mercury intramuscularly. Ordinarily, we use the soluble cyanide, but occasionally, and as a routine measure earlier in our experience (7), we used the insoluble salicylate. Arsphenamine may then be injected every day, especially if we have the patient under our control in bed at home or in a hospital. Injections of arsphenamine every other day for other cases may be given, especially to ambulatory patients or those unable to give up the time required every day. The interval between injections may be lengthened to four days, or even to a week, if it appears to us that the patient, by reason of the character of the reaction to medication or by failure of his kidneys, is a poor risk. In this respect we have more regard for the patient than for his disease. For similar reasons we would not ordinarily give mercury during the courses of arsphenamine, although occasionally, in robust, young syphilitics, we have done so with very favorable effects, and absolutely no ill effects. The main point in the treatment of the frank secondary syphilitic is to recognize that the disease has had a grand opportunity to get into every and any organ, tissue, and cell of the patient. Maximum treatment, rather than minimum treatment, should be insisted upon. The ordinary rules for cessation of treatment cannot be given or followed. Even after the eruption has disappeared, even after the Wassermann has become negative, treatment at regular intervals should be insisted on, and it should be good treatment—arsphenamine and mercury, not a few drops of potassium iodide solution at the whim of the patient, or some mixed treatment in the very convenient mixed treatment pill.

LATENT SYPHILIS.

The period following the clinical retrogression of the widespread secondary symptoms, either with or without treatment, we speak of as the latent tertiary stage. It is the stage of potentially active syphilis. Generalized eruptions may recur, or isolated lesions manifest themselves as gummata of the skin, bone, or any viscus. Latent tertiary syphilis is most resistant to treatment. The blood serology either remains persistently positive or becomes negative for short periods only. During the course of treatment the Wassermann may be favorably influenced, or the provocative action of therapy may act, and only after cessation of treatment does the Wassermann become negative. Resumption of treatment usually provokes the positive reaction. It is thought that well organized foci of spirochetes are present in this stage that neither the natural nor aided forces of the body are able to destroy. Treatment in the

latent tertiary (either Wassermann negative or Wassermann positive) syphilitic should be maintained periodically as a prophylactic against an uncontrollable outburst. The absence of symptoms may make it difficult to keep the patients under orders, but the importance of treatment should be successfully imparted. During this stage of the disease, periodical clinical and laboratory examinations should be made. The spinal puncture is recommended as being especially indicated in this stage in all cases.

The use of the Wassermann reaction as a routine measure in the practice of most physicians and in most hospitals has uncovered a large number of latent syphilitics who have positive Wassermann reactions. Not always, as mentioned above, does this mean that the presenting symptom is syphilitic in nature, and here, as everywhere else in medicine, clinical knowledge must come to the aid of the physician. However, many of these Wassermann positive cases are brought for antisymphilitic treatment, and it becomes a nice question to decide how the patient is to be treated. The age of the patient, and not necessarily the chronological age but the tissue age of the patient, is taken into consideration. The patient is not treated in a routine manner. Arsphenamine in smaller doses and at longer intervals is given, mercury is injected, and we prefer the soluble cyanide given every other day to the insoluble, more painful salicylate or grey oil. Potassium iodide by mouth in increasing doses, or sodium iodide intravenously in selected cases, is part of the medical program in the later stages of syphilis. Tissue reactions are watched for, especially those due to the medicine employed. We never fail to examine the urine before each injection of arsphenamine, and if there is any sign of a reaction of any kind, treatment with the old arsphenamine group is stopped, and after a proper interval we may change to the neogroup as being less toxic. The neurological examination in the late syphilitic is even more important than in the early case. The ophthalmoscope is utilized as a routine measure. The gait is watched. Sensation is investigated, and if the symptoms point toward nervous system involvement, the spinal fluid is examined early in the treatment course. After a series of intravenous, intramuscular and oral treatments, the fluid is again investigated, and if the indications are that the modes of treatment are inadequate for the case in hand, intraspinal therapy may be instituted according to the possibilities of avoiding further destruction of the nervous tissue.

ACTIVE TERTIARY SYPHILIS.

The treatment in this phase of the disease is little different from the preceding. Local ulcers or individual indications may require symptomatic treatment. The heart and bloodvessels may present changes which indicate changes in occupation, long periods of rest, or graded exercises. Involution of active gummata, gummatous infiltrations, and poor granulation tissue of broken bones, etc., is sought by arsphenamine and mercury and the iodide in doses compatible with the physical condition of the patient. We may give mixed treatment in these cases, or restrict ourselves to mercury injections or

even mercury by mouth, or inunction if more drastic treatment appears at all dangerous. Selected cases may be tried on office administration of arsphenamine; others may be restricted to bed for several hours before and after injection. In the main the doses are small, but they may be repeated more often; that is, over a longer period of time. The prevention of further lesions should be kept in mind always.

SUMMARY.

1. The patient with syphilis, and not syphilis should be considered by the physician when it comes to treatment. The tissues of the patient are worthy of respect, especially when one considers that the assault of the drugs needed in treatment is added to the tissue damage of the spirochetes.

2. Specific treatment of the syphilitic requires arsphenamine, or one of its newer salts, nearsphenamine, sodium arsphenamine, or silver arsphenamine. Mercury is also used in the specific treatment. The iodides are very valuable, especially in the later stages of the disease.

3. The use of arsphenamine in the prophylaxis of syphilis is a phase in treatment that is very important, and its results make it worthy of wider use. Its share in the public health aspects of this disease are especially valuable.

4. The intensive treatment in the early syphilitic, both when the abortive action and the quick and thorough sterilization of the patient seems feasible, is recommended for otherwise healthy persons with syphilis. Care in selection of the patient for this form of therapy is of first importance.

5. Modified forms of injection of arsphenamine should be given according to the patient, the reactions of his excretory organs, response to drugs, and phase of the disease process.

6. Iodides form a valuable addition, and the intravenous route should be considered, especially if large doses by mouth tend to upset the patient.

7. Systematic and systemic examination of the patient should be made at intervals, with especial reference to the cerebrospinal system. When indicated, the lumbar puncture for diagnosis and treatment is advised.

8. Routine treatments in syphilis should be disregarded. Every syphilitic patient should be treated as an individual requiring attention, and not as a case of syphilis.

15 CENTRAL PARK, WEST.

The Schellberg Treatment for Chronic Colonic Infections

By WILLIAM H. GALLAND, M.D., F. A. C. S.,
Croton-on-the-Hudson, N. Y.

During the past five years, O. Boto Schellberg has given well over thirty-six thousand colonic treatments. The results have been so favorable that I wish to present them to the medical profession.

Schellberg has cured many very obstinate cases of intestinal infection and ailments resulting from the absorption of bacterial toxins. He has demonstrated conclusively the practical value of the long rectal tube for irrigation and cleansing the large intestine. X ray photographs show clearly that such a tube may be passed through the colon as far as the cecum. We, as medical men, know that a large number of chronic pathological conditions are traceable to the absorption of putrefactive elements from the colon. These putrefactive elements are either the bacterial toxins themselves or are formed by the action of bacteria on proteid matter held in the colon.

The infant comes into the world with a sterile gastrointestinal tract. A few days after birth this sterile field becomes a garden spot for many bacteria. In the baby's gut two processes begin early, one fermentative and the other putrefactive. The lactic acid fermentative processes should be always in control, but if through faulty diet, carelessness, or impure food supply the butyric acid ferments and putrefactive organisms become predominant good health may be replaced by sickness and disease. As a child develops, the difficulty of keeping the proper healthful balance between the good lactic acid fermentative processes and the evil putrefactive becomes greater. We have with the coming of teeth more difficulty in keeping the oral cavity properly cleansed; meat, eggs and other foods causing more putrefactive activity in the gut are added to the diet.

Metchnikoff and Lane were among the first to trace chronic disturbances to infected or diseased colons accompanied by more or less displacement. They came to the erroneous conclusion that the colon was a useless remnant of a formerly necessary anatomical structure. Lane developed and advocated a short circuiting operation. He made an anastomosis between the small intestine and the sigmoid, eliminating the colon from functional activity. The result of Lane's operation discredited his hypothesis that the colon was an unnecessary part of the human digestive system.

Later and more logical researches have proved that the colon is worthy of its place in our bodies. While many disorders have their origin in the colon, this is due not to its being a superfluous part but to our misuse of it. Improper diet, overeating, lack of care for the hygiene of the mouth, and an attempt to conform Nature's excretory demands to the conveniences of our daily tasks, are a few of the abuses that combine to make such a burden to the colon that it ceases to function properly. We have resulting colic, flatulence, constipation, hemorrhoids; later, stasis, ptosis, general lack of tone in

the intestinal walls, a symptom complex of non-drainage.

Following, as a result of these disturbances, we have varying gastrointestinal symptoms, autointoxication with the many systemic diseases which follow this condition from the absorption of the bacterial poisons or the bacteria themselves, genitourinary infections from the passage of germs through the overstrained or damaged mucosa of the large intestine through invasion of the lymphatics by the infective bacteria. The colon, a useful organ, is converted by ignorance, carelessness, or disease into a menacing bacterial incubator.

The problem of keeping the colon actively healthy is now receiving much deserved attention. The treatment perfected by Schellberg from his original method has for its fundamental principle the use of lavage by which all parts of the large gut can be reached and cleansed by antiseptic solutions. Following the cleansing and the disinfection of its walls, he has carried the treatment to a cure by adopting Nature's means of preserving the balance of power to the beneficial organisms by planting in the cleaned and sterilized gut pure, healthy cultures of *Bacillus bulgaricus* and *Bacillus acidophilus*.

The treatment employed calls for a special but not complicated equipment: A three gallon irrigator connected with a three quart irrigator; a forty-six inch rubber rectal tube stiff enough not to bend on itself or be blocked by intestinal pressure, the tip sufficiently flexible to pass around the flexures of the colon; pure culture of the *Bacillus bulgaricus* and *Bacillus acidophilus* in the incubator for seventy-two hours; culture tubes for obtaining growths to determine the character of the intestinal flora.

The most satisfactory solution for the large container is found to be one tenth of one per cent. chlorazene, as chlorazene does not absorb readily. The temperature of the liquid in the large container should be kept at 37° C. One to eight thousand collene (a colloid of silver), one to thirty thousand chinosol may be used in the smaller tank. The temperature of this solution to be kept at 52° C. for use. The irrigators should be placed at least three feet above the patient. A large connecting tube from each passes through a three way valve connection. This in turn is connected to the rectal tube. If you wish to inject an oily substance, such as kerosene or turpentine, use a ten to twenty per cent. ichthyol solution as a medium. This emulsion is best forced through the rectal tube by a hard rubber syringe. The giving of a cathartic will aid in the cleansing process.

The observation has been that the sigmoid lies most generally in the central line, the normal inclination being to the left side; a few have been found on the right. As a rule, Schellberg begins the irrigation with the patient lying on the left side to gain the slight advantage of gravity. With the

rectal tube completely filled with the solution from the large tank, taking great care that all air is expelled from the tube, the tip is introduced into the rectum. Allow ten ounces to flow into the rectum, shut off, and permit the gas and any fecal matter present to escape. When the rectum is

can easily trace the gut as it fills, except where the abdominal walls are very thick and the intestine lies close to the back. Even in such cases practice will enable you to detect and trace it. When the tube has reached the splenic flexure, place your patient on his back, and, by the aid of the water

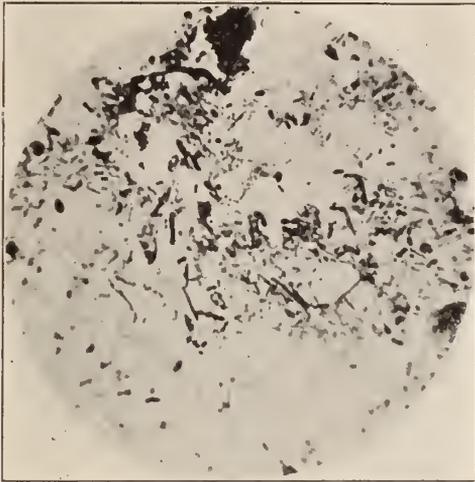

FIG. 1.—Culture taken before treatment.

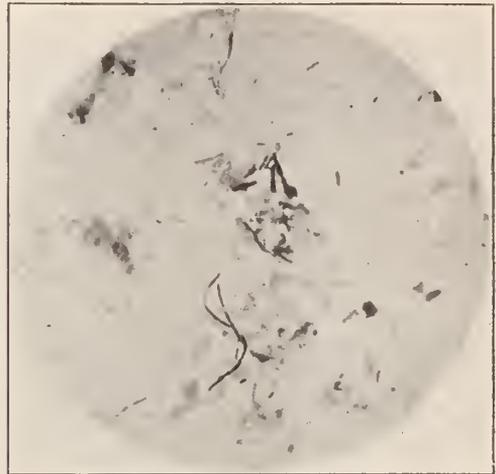

FIG. 2.—Culture three months after treatment.

clean of feces, turn on the water, dilate the gut, and begin feeling your way up into the intestine with the tube. Never try to advance the tube without the water flowing. After proceeding a distance, it is wise to shut off the flow and allow the expulsion of the bowel contents. Again turn on the water and proceed to advance the tube further. Go slowly, be gentle, persevere, and you will reach the ascending colon, and possibly even the cecum, no matter how misplaced, posed or pocketed the gut may seem. Gentle perseverance with the water pressure will allow you to reach your goal, unless there is some growth obstructing the gut.

pressure, make the turn. With a little patience, the tip of the tube will pass that turn into the transverse colon. Here one may need to turn on the solution from the small tank, and, by the heat of this solution, to excite upward peristalsis to carry the tube farther. Once beyond the flexure, irrigate before proceeding.

At first the treatments were begun solely for cleansing the gut. As Schellberg followed certain cases, he found that he not only cleansed the gut, but, where there was marked prolapse and displacement, even where the colon had been bound down by adhesions, persistence for a time freed the intes-

FIG. 3.—Culture at beginning of treatment.

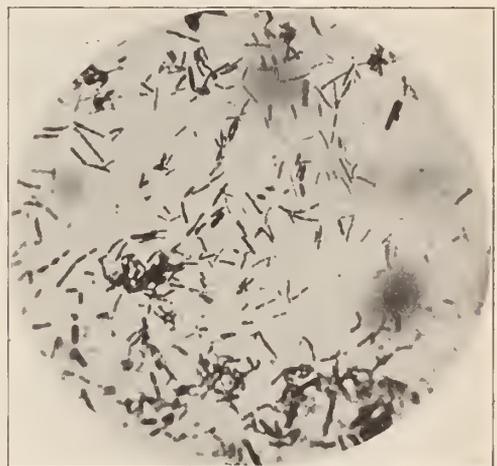

FIG. 4.—Culture during treatment.

One must learn to differentiate the feel between the tip of the tube striking a fecal mass and the wall of the intestine. If you do not learn to differentiate, you will not have great success with the procedure. As the water flows into the bowel, with one hand on the patient's abdomen, the operator

time, made it normally movable as well as relieving the sagging and ptosis. The correction of the sagging and ptosis was to be accomplished by a removal of the abnormal load of fecal matter and by the stimulation of the cleansing. The freeing of the gut from adhesion was not expected, but is

forming one of the most gratifying results of this treatment.

The study of conditions within the abdomen on the operating table and from autopsies teach that intestinal pockets are common in the colon, formed, as we know, when two inflamed surfaces lie close together in the lumen. The exudates from the

and resume their normal anatomical position after ten days of treatment. The parting of the binding adhesion may give the patient a sharp, stabbing pain, which is of short duration.

Schellberg has learned that until the colon is fairly sterile no lasting benefit is to be gained by the planting of the *Bacillus bulgaricus* or the *Bacillus acidophilus*. His method is to wash the colon daily with the antiseptic solution until the smears show a low bacterial count in the gut. The desired sterile condition is achieved in ten days with the average case. Streptococcus and staphylococcus organisms must be reduced to the minimum before planting.

Not infrequently a case is met in which the antiseptic solution causes such an irritation that one must stop the irrigation before the desired cleanliness is obtained. Into these irritable colons Schellberg introduces a one per cent. solution of dextrose, and a planting of twenty to thirty billion acidophilus and bulgaricus is made as high up in the gut as possible. After three or four of these daily plantings the intestine is usually quieted so that the disinfection can be resumed.

A few cases which had apparently been in condition for the permanent planting later showed increased or renewed streptococci and staphylococci after two weeks. In such, he disregarded his plants and renewed the disinfection. With the acidophilus on the increase with the absence of streptococcus and staphylococcus organisms, a chance of recurrence is not great. With ordinary care and diet,

FIG. 5.—X ray showing ptosis and misplacement of colon.

inflamed surfaces coalesce, consolidate, and form a band of tissue which contracts, pulling the two points together, forming a pouch in the intestine, the blind sacs making perfect bacterial incubators. (To these exudates, Schellberg has given the name intestinal interlining adhesions.) No cathartic or intestinal antiseptics given by mouth will clean these. Nor will the usual enemas remove the contents of such a pocket. The irritation caused by the bacterial growth in these pouches causes a reaction on the walls of the intestines, with the throwing out of a serous exudate which later becomes organized, forming the so-called adhesion, binding the colon to the abdominal walls or some intraabdominal structure. As a result, there is a colon which has not only lost its mobility but has become an incubator for bacteria and a producer of toxic material. He found that by passing the tube over these pockets daily with the stretching of the colon, his solution loosened these interlining adhesions, which were expelled, and at times would break loose some of the external adhesions. Sometimes this happened during the treatment, causing the patient sharp pain. More frequently it came after the lavage. With the opening of the pocket and the removal of the irritating accumulation, the adhesion bands immobilize the organ, atrophy, and give way. He has seen misplaced immobile colons become mobile

FIG. 6.—Ptosis and displacement of the colon shown by the x ray.

patients have shown a vigorous growth of acidophilus two years after this treatment.

For planting, Schellberg uses four ounces of a one per cent. dextrose solution, containing twenty to thirty billion acidophilus and bulgaricus, injecting this into the ascending colon or cecum. The tem-

perature of this solution should be 50° C., a planting made daily for from four to seven days, and then every second day for four or five treatments. The patient is placed on the right side for the planting. Before injecting the plant, be sure that all the solution used to introduce the tube has been expelled and that peristaltic action has become quiet.

FIG. 7.—Culture before treatment.

Following rectal plant the patient should remain quiet, lying on the right side for thirty minutes after the planting. After colonic treatment is discontinued the patient is instructed to continue taking active liquid cultures of *Bacillus bulgaricus* by the mouth.

In unbalanced states of thyroid secretion the careful physician has long recognized the necessity of carefully studying his patient for some foci of infection as a basic cause for, not only conditions of hypothyroidism, but hyperthyroidism as well. In cases of deficiency of thyroid secretion, or hypothyroidism, attended by pallor, languor, a general feeling of muscular weakness, and a general lowering of all body function, with enlargement of the gland, some very interesting observations have been made.

Some physicians have the teeth and tonsils carefully gone over before beginning the use of thyroid extract in cases of hypothyroidism, and some have even gone further and, realizing that the intestines might be the possible carrier of the infection, have attempted to clean them out by brisk purging. Often discouraging failures have followed the use of thyroid extract for reasons which Schellberg has been able to demonstrate in an interesting series of cases.

When patients presented themselves with typical symptoms of thyroid deficiency, coupled with distinct enlargement of the thyroid, the colon was thoroughly cleaned out and a healthy growth of *Bacillus bulgaricus* and *Bacillus acidophilus* implanted, and no further treatment was found necessary. The use of thyroid extract was not found necessary, because as soon as this source of infection had been removed the symptoms disappeared, and a decided reduction in the enlarged thyroid promptly followed. This emphasizes the importance in all unbalanced states of thyroid secretion first to clean

out the colon thoroughly by the methods followed in this treatment, never failing, of course, to give attention to other possible regions where foci of infection might be located.

Schellberg has been able to demonstrate that many of the debilitated patients show an excessive growth of staphylococcus and streptococcus in the colon. Schellberg also states that weakness and debility are not contraindications for his treatment. On the contrary, he has found such patients to be improved from the very beginning of the treatment. The amount of water absorbed by patients during lavage is marvelous. This water is rapidly eliminated by the kidneys; patients urinate quantities immediately following the treatment.

It has been found of decided benefit to patients suffering from pyelitis and certain forms of cystitis, because by this means large doses of urinary antiseptics can be given without the debilitating effect they have on the patient if given in any other manner. As an example, 380 grains of sodium salicylate can be thrown into the cecum at one dose. The patient will say that he can taste it within fifteen minutes, but he will be entirely free from the usual disagreeable symptoms a large dose by mouth would produce.

Schellberg has found that when a hot solution, given from the second irrigator at a temperature of 52° C., was thrown into the cecum, when the ileocecal valve was relaxed, some of the hot solution may by backward peristalsis be carried into the ileum. This at times will produce a chill which does not as a rule last long, and no serious consequences follow.

Finally, physicians must remember that the colon is a movable organ. It is not fixed, as is generally supposed, but can be moved by the rectal tube quite freely about the abdomen. A loop, twist, or kink of the colon may or may not be due to an adhesion, as more often the colon pulls itself into loops and as

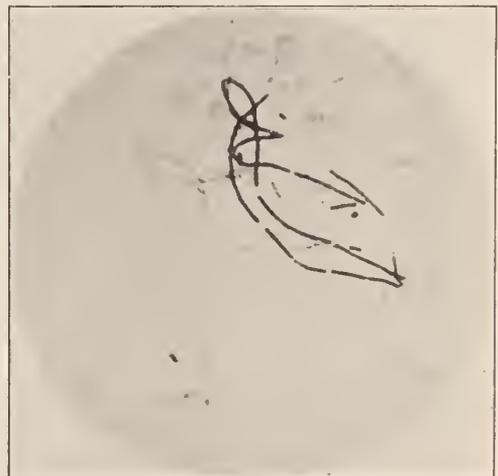

FIG. 8.—*Bacillus bulgaricus* a year after treatment.

easily uncoils, sometimes due to an extreme peristaltic action and sometimes in trying to expel masses of feces.

The x ray plates demonstrate the marked ptosis and misplacement of the colon met with in some of these cases.

A Coordination or Reestablishment Clinic in Hospitals and Dispensaries

To Furnish the Patient a General Survey, to Recognize and Remedy Minor, Associated, or Beginning Ailments, and to Raise the Coefficient of Efficiency in the Organism as a Whole

By J. MADISON TAYLOR, M. D.,
Philadelphia,

Professor, Physical Therapeutics and Dietetics, Medical Department, Temple University.

The enterprise of restoring health by no means ends with the repair of an obvious or urgent ailment. Ill health almost never is a single maladjustment of function, even in the most acute conditions. Back of the dominant feature lies yet other sources and weaknesses, earlier disarrangements, or persisting effects of disorder or disease. So true is this that human beings die only rarely of an acute disease but perish by reason of lowered planes of energizing, of overwhelmed defense reactions and vulnerabilities, constituting terminal phenomena. In adults, notably in those of late maturity, these phenomena are recognized as grouping themselves along certain familiar organ systems forming disorders—conscious or unconscious impairments—distresses or decrepitudes, in varying degrees but all capable of mitigation when approached judiciously.

We habitually deplore not being able to have had a seriously compromised patient under observation long before the presenting conditions had grown so complex or obdurate. When the patient has come under observation why not make sure that he or she shall not now escape until our utmost has been done to set them safely and confidently on their way? In private practice this enterprise can sometimes be carried out when we are permitted or encouraged to prolong our supervision. As the golden age of cooperation nears we shall be increasingly able to fulfill our plainly realized obligations.

In the instance of the hospital patient we chiefly have to do with those less alert to their condition, less able to afford the time and expense of completed restitution. These wage earners need, even more urgently, to achieve a sound plane of productivity. And yet this result can be handsomely approximated in the dispensaries among walking cases, by economizing the time of those still under treatment for one disability by directing patients to go from one special department to another, and thus secure relief from whatsoever ill defined disorder may be observed. Yet there often pass unrecognized manifold ailments or latent diseases, or beginning disablements, which deserve a thorough survey, recognition and treatment. The fact is, most patients shrink from admitting collateral ailments. They should be solicited and guided. Moreover, it is a fact, not commonly known, that any one can give their attention to only one misery at a time; there may be others but they sink into the background of consciousness. When the most obvious is removed, these others may come into the field of attention. By that time the dispensary patient yields to the urge to get home and remain at home, to cease complaining. Thus many minor and some grave maladies escape attention.

Students, or young graduates, could learn much from a complete systematic survey of such clinical material as this under the direction of a mature, experienced, all round teacher. Assuredly there would be found many clinical conditions which would profit by the searching out of subsidiary or collateral ailments or disabilities, notably such as come under the domain of so-called physical therapy, better orthokinetics, the modalities of motion, and of systematic developmental measures.

The enterprise of readjusting structures and functions, of reestablishing disordered reflexes through influencing the sympathetic as well as the spinal reflexes, is coming to be a large and increasingly significant domain of human betterment. Along with the physical are the mental readjustments, needed less or more in every protracted or chronic condition, and in most acute states, especially in those hypersensitive, apprehensive, or bewildered.

Hence in my judgment there should be a special clinic or clearing house to investigate the status of the case in its entirety, while undergoing treatment in any one department.

REASONS FOR A DEPARTMENT FOR HUMAN ADJUSTMENTS IN DISPENSARIES.

In every systematic dispensary group there should, in my opinion, be organized a special clinic to which should be referred practically all cases for determination of any latent or obscure phenomena deserving attention, for the remedying of distressing residua or complications, and for general and particularized integration.

Such a special department might be defined as a reestablishment clinic. From this the patient when coordinated or cured goes forth with some confidence that he or she has received a rounding out of advice, whereby a reasonable expectation can be had of restored health and productivity.

In any patient seeking advice, there are oftentimes subsidiary ailments long existing, overlooked, not sufficiently distressing to suggest seeking relief, but which might readily act as a factor for complicating the dominant distress or disability and in a degree nullifying the good effects of the advice already sought and received. Furthermore, such subsidiary ailments might frequently become starting points for yet further troubles, whereby the individual remains below par and unable to resume the full responsibilities of social or domestic or industrial undertakings.

While it may be assumed that the dispensary chiefs, specialists in any one of the various lines of medical endeavor, do try to discover all collateral disorders, it is only too true that, in a crowded serv-

ice, many essential points or weaknesses or ailments do escape attention. It is also true that when some factor is suspected outside the purview or jurisdiction of the chief, the case is, or can be, directed to one or the other of the definite departments. Too often, however, in the hurry many escape needed attention, after the major problem has been disposed of.

Provision should be made for any concurrent ailments, mental as well as physical, complicating the problem and which deserve, indeed demand, attention, in the best interests of the individual as a suffering, or an inadequate human being. Here we have the justification of the department suggested, a clearing house for not only the conditions now recognized as conventional, but for that large group of reflex conditions which as yet are only grudgingly admitted to exist, or even are frankly denied.

In such a clinic the first work would be to search for findings, to appraise the possibilities for rendering service, and for affording instruction to students in solving unfamiliar yet significant problems. Ample justification and special classification would in my opinion be found. All cases should, indeed, be referred to the reestablishment clinic for extra attention to collateral, subsidiary or complicating conditions and their remedy. The nature, or character, of these disabilities will be mentioned later.

Relief along these lines, moreover, might readily go far toward fortifying the individual to recover constitutional vigor and do greater justice to the primary advice. The kind of counsel I picture in my mind is not only that which could be got at the so-called medical dispensary but something much more, and outside the domain of that department as now constituted or executed.

In such a clinic for reestablishment an all round, careful survey would be made of the organism as a whole, a visualization of the person and personality in its entirety, or at least so much of it as might seem needful in order to determine whether the various parts, limbs, back, neck, static and kinetic mechanisms, are in order, and wherever is disorder, distress, disability or maladjustment, to apply suitable measures for overcoming them, or to refer the case for particular treatment to the special department provided. Most ailments found will, in all probability, come within the scope of this special clinic. The scope of endeavor includes disorders of personality as well as of the material organism. Hence some knowledge is needed of neurology, of psychopathology, and of psychotherapy along with a full appreciation of biophysics and of straightening out maladjustments in the body as a biomechanism, a mass of reflexes, in short, a balancing of the defense mechanisms. To make plain this concept, I have offered the descriptive term *orthokinetics* or the rectifying of maladjustments through the modalities of motion, manipulation, replacement, manual adjustment, and guidance in motor performance; in short, volitional training in the active or kinetic phase, or in the reverse, the resting or akinetic phase, also by quieting the overacting or underacting reflexes, the release of tension, of tonic protective spasm, of intraarticular pressure, and al-

ways along with specific or particularized motor performance in accord with design and function.

Of similar importance is the undertaking of readjustment of the disorders of personality, of emotion, of the release of repression, or of suppression, of restoration from the effects of mental conflicts which enter into most of the problems of disordered life. Such measures for relief are in no sense a thing apart but implicated in the web and woof of most, if not all, human miseries and disabilities. There is always available the neuropathic or psychopathic departments for those in whom these features are pronounced and obdurate.

The qualifications of chief for the special reestablishment clinic thus would include fair familiarity with, and skill in, several special fields of medical art, as well as science. He and his assistants should be men or women of forceful personality, warm sympathy, ripe judgment, of ample and varied experiences, which should include some years in the active general practice of medicine in order to achieve powers of visualization, perspective and proportion. It is also desirable that they should have certain endowments of deftness, of dexterity, of motor common sense, and of particularized aptitudes in the domain of economic conservation, reconstruction and coordination. Also a capacity to win confidence, loyalty, cooperation; to enhance selfcontrol and selfdirection, selfsacrifice, and faithfulness in the performance of duties, obligations, contributing to recovery of selfdetermination and powers of worthy achievement.

They should have nice powers of observation and interpretation of externals, of expression, of attitude, of demeanor, of physical proportion, of symmetry, of variants in local tone or loss of tone, in color alteration, in short, of significant appearances visible to the eye, or to touch, or muscle sense (*kinesthesia*), and how they shall be appraised.

They should possess high endowments and trained aptitudes in tactile apperception, in weighing the evidence of resistance to the hands, and in rightly inferring what is amiss and what must be done in the way of physical adjustments, of setting in order disordered biomechanisms through forms and modalities of motion (*orthokinetics*). Here we have those fundamental means of restitution among which are release of repressed reflexes, of tonic protective spasms, hence of transferred pains, of faulty attitudes, of intraarticular overpressures, of compressures exerted on tubular or hollow organs, of displacements of viscera, of junctures, of nerve trunks, of subsidiary centres and similar biomechanistic problems.

Included are the resources of replacing parts in positions of advantage, of tact and persuasiveness in eliciting economic motor responsiveness, of developmental volition, in precision of purposeful performances, whereby so much of cure as can be shall be achieved. The straightening out of entanglements or decrepitudes, lameness (*orthokinetics*) is both of the mental and of the physical. In between the two lies the reflexogenic domain.

The right working of the human body depends, in large measure, on nicety in equipoise and of instrumentalities; next on the consciousness of the mus-

cle structures in organs and this again upon intelligence of reflexogenic groupings. Here set forth is a field for clinical endeavor as yet only suggested but growing in certitude and usability. We hear much of the vegetative and the autonomic nervous systems, but they work through sensitive somethings which we appreciate as reflex responses. These suffer varied and complex forms of disorder, but are capable of helpful readjustment and regulation, and through them are capable of being relieved a multitude of disorders of the vegetative and reproductive life.

It is entirely possible usefully and economically to control the involuntary motion in the tubular and hollow organs, the ebb and flow of fluids, of blood, lymph and the cruder intestinal and visceral contents.

The accessible avenues are the subsidiary centres in the paravertebral tissues whereby vasomotor, visceromotor and sensorimotor regulations can be achieved. In vasomotion we can promptly release or reconstitute vasomotor imbalance, so of the visceromotor and sensorimotor imbalance. There is also the manual or mechanistic instrumentalities of releasing many inhibited energies, of putting them back on their job, encouraged, serene and efficient.

Finally there are large possibilities for raising the plane of energizing in an individual from that on which he has heretofore functioned, and to reach a yet higher plane, partly by what has been said, i. e., placing parts in positions of advantage which had come into those of disadvantage for performance. This is to be done through attention to developmental measures both physical and psychical. In most patients latent obstacles exist to full health which can be advantageously removed by taking a perspective view of the entire organism and by applying suitable regulatory measures. In order to make my meaning more clear, I may cite some of my personal experiences.

Patients come to me, often sent by a specialist, an internist or a general practitioner, suffering from an ailment just outside the line of their familiarity of which I am able to determine the character and extent and which I am privileged to relieve or to cure. The patient returns to the primary adviser and may remain under his care, as well as under mine, till I am done or he is done or both. Not seldom the relief I am able to afford gives material aid to what he is doing for the recovery of the disordered organ or part, or even of a system, as of the cardiovascularrenal or genitourinary or digestive or metabolic system. Any one can work in complete harmony with the adviser and supplement his work.

In this connection may be mentioned a few of the conditions thus surveyed and repaired and which retroact on the sensory or energy reserves:

Local pains, disabilities, dysfunctions, backaches, headaches, neckaches, foot troubles, lameness, many of which are due to muscle pains (fibromyositis) or to minor disturbances of joints, intraarticular pressures, muscular imbalances, transferred pains, pleural, and other adhesions.

Also a large number of ailments due to impaired tone in the abdominal muscles, anterior or posterior, whereby digestive dysfunction occurs preventing re-

sponsiveness to pharmacogenic remedies. They may have existed long before the major or dominant disorder or distress, acting as part of the general handicap. Unless removed before discharge from hospital after appropriate and otherwise adequate treatment, dissatisfaction results and retroactive disturbances.

The whole topic of maladjustments is thus seen to be obviously important, and becomes of vivid interest to those who have directed their attention that way. On a later occasion I will elaborate the subject and submit a category or memorandum of clinical phenomena.

Briefly, then, let me express my confidence that when the subject of readaptation is carefully considered, it will be found to grow in importance and usefulness. Indeed it is the logical outcome of efforts at making medical art a complete and satisfactory form of beneficent welfare work. Men could be trained in readjustment whose observation will prove of vast benefit to them in future professional careers. Also the potential of the profession, the esteem in which they are held by the public, will become stronger, fuller, more dynamic. There will be far fewer loose or raw ends left to produce dissatisfaction or recrimination.

The point for particular attention is to let no element of disablement escape recognition, explanation or relief. Many points may seem trivial but they are capable of producing, or contributing to varied miseries and retardations of recovery. They may well lie outside the purview or jurisdiction of the former adviser. If suspected they could well be referred to some suitable department.

In the absence of suspicion, or in a spirit of patient endurance, the individual departs carrying away various retarding residua, disabilities, distresses, and then tends to blame the hospital or the special adviser and to ascribe unjustly the associated disorders to professional omissions or to carelessness.

It is a well established fact that one can only be conscious of one source of pain at a time; when the one is relieved another may come into the foreground of attention. So of tenderness, aches, asthenias, chronic local overstress, disordered sensations of diverse kinds. These come into active consciousness as other are relieved. There may be many of them; especially in protracted or chronic or complicated disorders, or after operation. Furthermore many scarcely noticed ailments become the starting points of severe, unremediable disease.

1504 PINE STREET.

Charcoal and Laudanum.—I. Simon (*Gazzetta degli Ospedali e delle Cliniche*, December 4, 1920) describes two strengths of the preparation, one of two per cent. and the other of four per cent. It is especially efficacious in the treatment of enteritis, as it promptly alleviates the cramplike pains of the condition and, when combined in this way, a much smaller dose of the opium product is necessary than when it is used alone. The action of the animal charcoal is to absorb and fix the toxins of the infecting bacteria.

An Unusual Hypophyseal Syndrome*

By E. D. FRIEDMAN, M. D.,
New York,

Adjunct Neurologist, Bellevue and Mount Sinai Hospitals, Instructor in Neuropathology, University and Bellevue Hospital Medical College.

The following case has recently come under my observation, and it presents so many unusual features that it was deemed worthy of recording in the literature:

CASE.—E. C., aged nineteen, student. The chief complaints were dwarfism and obesity, of nine years' duration, hypertension, recurrent pains in the region of the spine for six months. The family history showed the parents and one sister to be short and stout. The patient was the third of seven children. One brother suffers from petit mal. The previous history revealed measles and scarlet fever. It was not known whether the kidneys were involved at the time. His birth was normal. He developed satisfactorily until the age of nine years.

Nine years ago the patient began to grow stout. He gained much weight in two months. Since then there had been very little growth in height. His abdomen became pendulous, his fingers stubby, feet remained small, and face became ruddy. In 1915 he was treated by an orthopedist, who administered thyroid extract for over a year. He grew about two inches in height in that time. The treatment was then stopped. He felt well and went to college. Six months ago shooting pains developed in the region of the spine and chest. His urine was then examined and showed so-called kidney trouble. About one and a half months ago a pain developed in the right upper quadrant of the abdomen. This seemed to shift with change in position, and lasted about two weeks. He had shortness of breath and palpitation of the heart after exertion. His speech became somewhat hesitant. He had some impairment of memory. There was tremor after exertion. He had dimness of vision for the past two months, and occasional headaches. Nocturia was present, but no polydipsia.

The physical examination showed the patient to be short and obese, with erythema of the face and a pendulous abdomen. The mammae were well developed and the fat distribution was of the feminine type. There was an overgrowth of hair at the bridge of the nose, and the body was covered with fine lanugo hairs. The total length of the patient, standing, was 136.5 cm. (The normal for this age would be 175 cm.) His weight was forty-six and four tenths kilos. The pupils were normal and fields normal. There were two minute retinal hemorrhages at the outer side of the left disc. The teeth were a bit spaced and irregularly placed. The tonsils were moderately enlarged. The thyroid was not palpable. The lungs were negative. The heart was somewhat enlarged to the left. The aortic second sound was accentuated. The abdomen was distended. The liver edge was just palpable. The genitals were small. The fingers were stubby. The

knee jerks diminished. The skin showed ringworm in the axilla and pubis, erythema and telangiectasis of the face and striae distensae on the abdomen and thighs.

The laboratory findings were: hemoglobin, 95 per cent.; red blood cells, 4,860,000; white blood cells, 13,400; polynuclears, 76 per cent.; lymphocytes, 19 per cent.; large mononuclears, 3 per cent.; transitionals, 2 per cent. Blood pressure, 198/110. Phenolsulphonephthalein excretion test showed at the end of the first hour 35 per cent., and at the end of the second hour 24 per cent. Chemical examination of the blood showed: Urea nitrogen, 12.6; nonprotein nitrogen, 46.6; uric acid, 2.7; creatinin, 2.1; sugar, .240; cholesterin, .308 in 100 c. c. of blood. Wassermann of the blood was negative. The basal metabolism was 39, i. e., minus 5 per cent.

The patient was admitted to the service of Dr. Libman at Mount Sinai Hospital, where some of the observations included in this report were made. The dental examination showed that the lower molars were unerupted and impacted. The upper first molar was found to be devitalized and was extracted. There was considerable bleeding, which was finally stopped with thromboplastin. Temperature varied from 98.6° F. to 99.8° F.; pulse from 90 to 100. Urine showed a specific gravity of 1.010 to 1.020. There was a faint trace of albumin, sugar was present, no acid bodies. Microscopic examination was negative. Adrenalin test of Loewi for pupil dilatation was negative. Oculocardiac reflex was positive. No slowing or sweating after pilocarpine. No effect after atropine. Adrenalin test was not made, due to the high blood pressure. Libido absent; only an occasional erection. Electrocardiogram showed a left ventricular preponderance, tachycardia and sinus arrhythmia. There was slowing of the rate on holding the breath and after vagus pressure. There was a slight alteration of the size and shape of the P wave (instability of the cardiac pacemaker). There was an unstable vagus and sympathetic balance.

X ray examination of the skull showed undeveloped sinuses, the left being opaque. The sella was normal. Posterior clinoids as well as the bones of the body of sphenoid appeared markedly atrophic and thin. Entrance to the sella was narrow. There was a dense shadow in the middle fossa. X ray examination of the chest showed a shadow at the root of the neck, extending up from the aorta, and probably due to the large vessels. The aorta showed considerable dilatation for an individual of this age. This was probably due to the hypertension. X ray examination of the hands showed development of bones such as we usually see in a person of thirteen (epiphyseal lines were still present). X ray examination of the kidneys and lumbar spine was negative.

*Report presented at the meeting of the New York Neurological Society on January 4, 1921.

The patient's stunted growth pointed to a deficiency of the morphogenetic principle of the anterior lobe of the pituitary. The posterior lobe was probably responsible for the hypertension and glycosuria. The adrenal was also concerned in these abnormalities. Certainly the tendency to hypertrichosis and high cholesterolin content of the blood pointed to involvement of the adrenals. That the thyroid was implicated is shown by the fact that ossification of the epiphyses was much delayed. The skin, too, was rather dry. There were disturbances in the sex glands as shown by the diminished libido and disturbance in potency.

Thus far two main clinical types of pituitary disorder had been known, hyperpituitarism with resulting acromegaly described by Marie, and hypopituitarism leading to the syndrome of Fröhlich. Recently Reichman (1) described another type of pituitary disorder very much like this case. His patient differed from ours in that he did not show obesity and had a bradycardia instead of the tachy-

cardia seen in this patient. At the postmortem examination his patient showed adenoma of the hypophysis. During life it seemed as though there was hyperfunction of the hypophysis and adrenal, and hypoactivity of the thyroid. Probably as time goes on more of these syndromes will be described, depending upon the repressing or accelerating effects produced upon the other glands of internal secretion. In view of the tremendous interrelationship existing between them, we shall probably always find pluriglandular manifestations. The dominating changes may be ascribed to vital disturbance of one of these glands, but there are usually seen evidences of deranged function in most of the others. The physiology of these glands is so intimately concerned with the problem of life itself, that definiteness in this field is still far from the realm of possibility.

74 EAST NINETY-FIRST STREET.

The Etiology and Elimination of Tuberculosis

By G. LENOX CURTIS, M. D.,
New York.

Ever since Koch, in 1890, announced his discovery of a probable cure for tuberculosis, I have given this subject special consideration, not alone with a view to developing a cure for tuberculosis, but also to understanding underlying conditions that predispose to the disease. So profoundly did Koch's announcement impress me that I remained a year in the clinics of Berlin and Vienna where I had daily opportunity to see patients treated with tuberculin and to watch the results. I followed closely the effect of the treatment and noted the terrible destruction of life that followed the injection of this lymph into unfortunate patients who flocked to the cure. As a result, I came early to the conclusion that the principle of injecting the deadly bacilli of tuberculosis into persons of tuberculous tendency was wrong. I was further convinced of this from witnessing autopsies, where I realized the destructive effect of the treatment upon the system. For not only had the disease ravaged the organs, but even the marrow in the bones was dissolved into a culture bed for swarming masses of tubercle bacilli.

During the thirty years that have since intervened I have watched with keen interest the persistent efforts of those who have followed the great German leader of science along the false trail of hope, until the idea finally possessed me that the underlying cause of tuberculosis might be similar to the causes of other suppurative and so-called incurable diseases, differing only in its stage of development. To this end I quietly worked.

The facilities of the great clinics of Berlin and Vienna, where I discovered the etiology of tuberculosis in 1890, and of the Post-Graduate Medical

School of New York, to which upon my return I became attached, afforded me exceptional opportunities for continuing these studies and brought me also into contact with a number of allied diseases—notably cancer, gangrene, pyorrhœa alveolaris, and diabetes.

While in Germany, I gained some knowledge of the examination of the blood, but my persistent question, Does not the baking of the smear destroy some conditions that render an accurate reading of the blood impossible? was never answered satisfactorily until in 1892 I became a student of the American system which I consider more trustworthy than the baking and staining process. By this method only freshly drawn blood is examined which is immediately photographed for future reference. Following this work in the examination of freshly drawn blood, I was able to find indications of diseases that the old drying and baking process completely obliterated. Finally I obtained convincing proof of what I believe to be the underlying cause of tuberculosis, as well as of gangrene, pyorrhœa alveolaris, diabetes and cancer.

My convictions are based not alone upon my impressions, microscopic and microphotographic verifications, but upon long years of clinical experience. As further proof of my views I quote from Jenner: "A healthy boy, vaccinated May 14, 1796, which began the era of vaccination, died a few years later of phthisis." Stefansson, the Arctic explorer and discoverer of an isolated tribe of phenomenally robust Eskimos, states that venereal disease or tuberculosis is unknown to them. As a result, all my tuberculous patients, several hundred in number, in all forms and stages of the disease, who could have

proper care and treatment, as hereinafter outlined, were cured and remained cured.

Now, some products of the disease are less hardy than others and oxidize more quickly, for instance, tuberculous matter as found in freshly drawn blood is not found when the smear is dried. Therefore,

FIG. 1.—Tubercle bacilli found in the blood of a patient suffering from tuberculosis.

in order to see all the blood contents, the specimen should be immediately covered after being drawn, and kept at body temperature and quickly examined. For if the warm air in the lung oxidizes the blood, how much more quickly will the cold atmosphere change the form of the delicate products, or the primary signs of disease it contains? The technic in securing these examinations should be accurate and painstakingly aseptic.

In 1896 I first secured photographs of blood from tuberculous patients that distinctly showed the bacilli of tuberculosis, and again in 1902. I herewith submit two pictures (Fig. 1 and 2), one showing two normal bacilli, and the other showing many bacilli undergoing segregation. The patients from whom these blood photographs were made, were referred to me as hopeless, and from general appearance one might well accept the false prognosis. Yet both recovered their health and are now living and well. This, I believe, is the first authentic record of tubercle bacilli being discovered in living blood, also the first photographs of bacilli in living blood.

In 1889, when assistant in bacteriology to Ernest La Place, in Philadelphia, he demonstrated to me that certain germs would not die when placed in a one to one thousand solution of bichloride of mercury, but would be immediately destroyed when the solution was even faintly acidulated. I asked him why not acidulate the body when attacked with disease that progressed under albuminous conditions? He replied that such a course would be likely to result

in phlebitis, and possibly in death. However, the idea of acidulating the system affected with diseases depending upon albumin, grew upon me, and it was not long before I experimented with this method, and with astonishingly successful results.

I was born of healthy parents and was always rugged. During childhood I had measles and mumps, but no other diseases until I was in the twenties, when I had typhoid fever. I never had venereal disease. During the epidemic of smallpox in New York in 1892, rather than be responsible for carrying the disease to the homes of my patients I felt it my duty to be vaccinated. This marked the flight of my robust health and all but caused my death. I was vaccinated with fresh material from the laboratory of the board of health, vaccine that had passed the test of the double and treble \times refinery. I was very ill. During the first two weeks my temperature ranged from 106° to 110° . Another week passed before I could resume practice, or could drag myself back to my class. Long vacations in the woods kept me alive, but my shattered health caused me to abandon teaching, and finally to give up my practice and seek recovery in the sunny West. I had gradually gone into a decline until no hope of my recov-

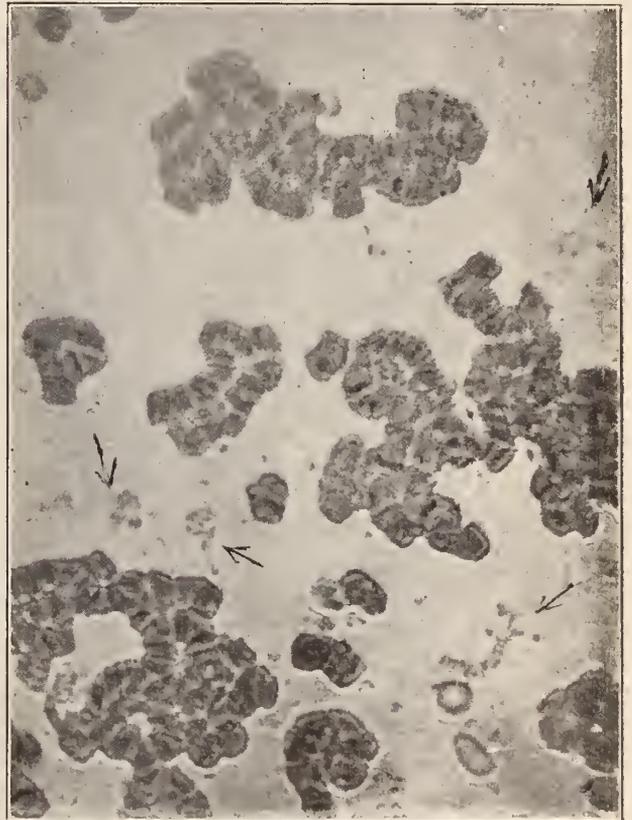

FIG. 2.—Tubercle bacilli in the blood.

ery was entertained by my physician friends, who pronounced me in the third stage of tuberculosis. The sunshine and ozone of the prairies helped me greatly, however, and within a half year's time I was able to return, to work out the discovery that ozone was the most potent factor in exterminating tuberculosis.

Prior to being vaccinated I had been a great sufferer from rheumatism, and for several months was practically helpless, being unable to dress or feed myself. Soon after vaccination, however, this condition subsided, and when tuberculosis made its appearance rheumatism had disappeared.

Examination of urine and saliva showed that my secretions were alkaline, but it was not until 1896 that I realized that rheumatism and tuberculosis were antagonistic, and that both could not persist at the same time. I found that overacidulation of the system was always present during rheumatism and was responsible for the fibrin which alone causes rheumatism. I therefore treated all cases of rheumatism with antacids, soda and ammonia, and all cases of tuberculosis with acids, until the system was acidulated. I found that by this method the alkalies dissolved the fibrin, while the acid killed the bacilli and reinforced the system against the development of tuberculosis. But it was not until several years later that I realized that by feeding albuminous substances, milk and eggs, for instance, to tuberculous patients I was unable to fully acidulate the body and to keep it acidulated until they were well, although I prescribed acid food denied rheumatic patients.

The usual classification of the stages of tuberculosis I consider too inaccurate for scientific purpose, so I divide them into five instead of three stages, as they are generally described. In the first stage, the preclinical stage, the mucus peculiar to tuberculosis, designated as tuberculous matter, is present before the slightest ordinary clinical manifestation is evidenced. This is the most important stage in which to make a diagnosis, for here a prognosis of the future health of the patient can be made with assurance. In the second, the incipient stage, the first ordinary signs appear, such as pallor, bronchitis, hoarseness, slight cough, slight contraction or possibly dullness of the apex of the lung, increase in respiration, tenderness of the spinal accessory nerves, due to luxation of the vertebræ, especially dorsal or cervical vertebræ, loss in weight, constipation, dysmenorrhæa, amenorrhæa, anemia, dullness of the eyes, and other well known symptoms. In the third stage bacilli are found, with slight or occasional night sweats, pronounced dullness, râles, abnormal temperature, expectoration in the morning, occasional surface ulcerations, bone necrosis, meningitis (which can be detected only with the ozone electrode) and abdominal and pelvic tenderness. The fourth stage shows many displacements of the spinal vertebræ, sometimes curvature and extreme tenderness, meningitis, peritonitis, and cessation of the menses. This is the so-called hopeless condition, in which most patients die. In the fifth stage, all the recognized symptoms of the fourth stage are increased. Also there is frequently tuberculosis of the bowels, pus filled cavities in the lungs, liver, and kidneys, empyema, profuse night sweats, gangrene of the lungs, extreme emaciation, inability to take or retain food or water, respiration from 48 to 60 a minute, parts of the lungs not consolidated filled with râles, daily temperature up to 105° or 106°, pulse from 150 to 300, and death hourly expected.

All tuberculosis patients have one or more other diseases which complicate the case. The one thing that is persistently present is subluxation of the spinal column, which is not confined to tuberculosis but is found in most chronic diseases and is often the direct cause of the same. The cause is tertiary syphilis and is usually contracted through vaccination against smallpox, hence the white plague. But it is often inherited.

In my judgment a great error in treating tuberculosis is made in sending the patients to the country, where physical comforts and proper medical attention are often lacking. Most of such patients die, and few are even helped. In the early stages of the disease, woods or prairie life alone have been known to effect a cure in some cases, but home comforts and family associations are essentials that should not be lost sight of. All my patients, except a few in my early practice, were treated in this city, some of them leading a basement and sweatshop life and without a direct ray of sunlight, except when en route for treatment.

In all, I have treated more than seven hundred cases of tuberculosis, the majority of which were in the fourth or fifth stages. In only one, fifth stage case, could the patient have the care necessary for recovery, but after several years of persistent effort she resumed the care of her home. She never became robust, although able to resume social life, and later traveled across the continent. She lived fourteen years and died following apoplexy. Vaccination and a half inch displacement of the atlas of the spine were the direct causes of her trouble. The vertebra was so completely anchored in the false position that it resisted all efforts to replace it. The lower lobe of the left lung was finally destroyed by pus, which by surgical means was drawn off. Immediate and rapid relief followed with a drop of temperature from 105.5°, where it had been daily for months, to normal, where it remained. When this patient began treatment, only the extreme apex of the right lung appeared in action, respirations were never less than 48, temperature 103° to 106°, pulse 150 to 300, as near as could be calculated. With the exception of a number of cavities, some of which were large, all but the lower lobe of the left lung resumed a normal condition. The chest expansion which, after the tuberculous matter had been thrown off, was but one and a half inches, doubled under physical training in three months, and the shoulders widened three and a half inches.

Antisyphilitic treatment was employed in most of the cases, but in the first and second stages the patient will recover without it, providing they can have ozone treatment, or possibly out of door life in a dry atmosphere away from tuberculous patients, take regular pulmonary and general physical exercise, and observe the natural laws of health.

Patients in the second stage should have the acid treatment, avoid milk and eggs, tuberculous meats, and foodstuffs gathered from farms where tuberculosis has been detected, and take mild antisyphilitic drugs. The method of putting tuberculous patients to bed or confining them without an opportunity for physical exercise or outdoor life, is

strongly to be condemned. Tuberculous patients properly treated usually get well within four months on intravenous injections of salvarsan, one injection, followed by red iodide of mercury, one sixth to one fourth grain three times daily. Aqueous solution of iodine three times a day or more often as conditions indicate; ozone once to three times a day over the entire body, but especially the spine, lungs and head; substantial but palatable diet as soon as it can be tolerated, and in small quantities at a feeding; no creosote, codliver oil, and, so far as possible, no predigested foods should be given. If the temperature is high give whiskey sparingly. Wash out the stomach and rectum twice daily with a hot nonpoisonous disinfecting solution. All acid food and drink that is acceptable to the patient should be given. Acidulate the system rapidly and maintain this condition throughout the treatment. Administer from five to twenty drops of the clear acid mixture in a glass of water several times daily, preferably on an empty stomach.

Inhalations by atomizer, several times daily, of equal parts of lactic, acetic and aromatic sulphuric acids, one to four drams, sufficiently diluted, assist greatly in acidulating the blood, and in preventing hemorrhage. It also dissolves the mucus and pus, and kills tubercle bacilli and other bacteria which obstruct the breathing, and facilitates expectoration. Following the inhalations, expectoration becomes easy and free, and in a few days the tuberculous matter in the lungs is dissolved, and is coughed up in great quantities with ease. Pus cavities are emptied and gangrenous portions of the lungs thrown off. On two occasions I saw as much as half a pint of gangrenous lung tissue expelled at one time, along with a large quantity of pus.

Annoying conditions such as tooth trouble, eye-strain, and constipation or diarrhea, must have careful attention. When coughing is too exhausting, a very small dose of heroin may be injected. The calm that follows this administration affords rest, renews strength, and eventually produces sleep. The daily use of compound oxygen, especially in early stages and in hemorrhage, is of great value. As soon as the lungs are free, breathing exercises should be adopted to strengthen the long unused portion of the lungs, and permit of a greater amount of air being taken in.

Cracked wheat cooked three hours, eaten with syrup or with cream and sugar, bread from unrefined flour, butter, pure olive oil, vegetables and fruit that produce a minimum of gas, meat from healthy animals, and alfalfa nutrient are all excellent foods. The value of onions, asafetida, and garlic, cannot be estimated. I have made free use of them in all infectious diseases as they seem to have a decided influence on pathogenic conditions. If tuberculosis is rarely found among garlic eating people, it may be attributed to this vegetable. Plenty of pure water should be drunk always. The bodily temperature should be kept equable by hot and cold baths and proper clothing. Pleasant surroundings should be maintained and the patient encouraged to believe that recovery will be rapid. If there is a hemorrhagic tendency, give erigeron oil in small doses two or three times daily,

or turpentine or nutmeg, and inhale spray of the acid solution. From the first treatment by ozone, clinical signs of improvement are observed, and in six weeks, with daily or thrice daily ozonizations of the body, patients in the incipient stages apparently recover, while the consolidated lungs of those in the third stage are usually opened, the bacilli cleared, and the patient dismissed as cured in four months. Those in the fourth and fifth stages require a longer time, but ninety-four per cent. of the patients are usually well by the fourth month, while the remaining six per cent., provided every care can be given them, are free from all tuberculous symptoms in from six months to three years. The common practice of admitting patients in all stages of the disease under one roof, or a colony, is to be condemned.

Following twenty-two years of practical work and observation with tuberculous patients, I am satisfied that the tuberculous matter can be got rid of, and the patient rendered immune from the disease, provided that the treatment indicated by this etiology is properly administered.

This article was accepted in 1919 by the NEW YORK MEDICAL JOURNAL, but not published until now. In September, 1919, while in San Francisco I met Dr. Albert Abrams, and discussed with him the etiology of cancer. At that time he was unwilling to accept my findings as pointed out in an article published in the *Medical Record* of June, 1906, that syphilis is the cause of cancer.

During July, 1920, while visiting the laboratory of Dr. Abrams, he told me that since we had last met he had verified my contention that the etiology of cancer was syphilis, as he had found syphilis in all cases of cancer coming under his observation during the year. On this occasion I told him that the indirect etiology of tuberculosis was the same as that of cancer. This statement was also regarded dubiously. However, he was willing to be convinced, and immediately called to his laboratory several cases of tuberculosis then under treatment and applied his electronic reactions method for syphilis, finding it present in all of the cases. Therefore he accepted my theory.

In *Physico-Clinical Medicine* for June, 1921, appears an article by Dr. Abrams, on vaccination, in which he substantiates my claim that the vaccine ordinarily employed against smallpox contains syphilitic virus. All but three of many tests made of vaccine obtained from four laboratories contained congenital syphilis. He also reported the case of a boy whose blood showed no reaction of syphilis before vaccination but did show it nine weeks later.

I cite these findings of this eminent pathologist as further verification of my assertion that vaccine, as employed against smallpox, contains syphilis and is the primary cause of the white plague and that syphilis is the primary lesion that allows the development of tuberculosis. It is interesting to note that in all but two of the tests made, there was a reaction of streptococci and staphylococci and that there was a positive variolar reaction in all specimens.

SOCIAL MISFITS

We were privileged (though the privilege was not a pleasant one) to visit recently a home and school for subnormal people, children and adults, where, from all over the world, were gathered all manner of specimens of human beings, or of beings in all stages on the way toward the human state. Helpless, immature animals many of them; fools some were once called, and these were of a kind once in demand for the entertainment of princes—by any name they may be called they are none the more pleasant to contemplate, though they are of all degrees of distressing appeal. The institution in question has done somewhat more than house and feed these unfortunates—it has been a leader in the study of its inmates with a view toward making the most of them, and, if possible, of discovering means of reducing the oncoming crop of such specimens, and of influencing public opinion to make larger and better economic provision for those children now in institutions who, later, may be cast upon a world for which they are unfit and in which they may do untold harm.

The five hundred inmates of this institution are gathered from the four corners of the earth, but that does not mean that one must search the antipodes to find such an array of unfortunates. If we may trust the figures of students, one community of fifty thousand persons can furnish as many subnormals, even if there be not the variety of cases found in this school. The number depends, of course, on the tests we apply in determining mentality, and the human mentality is a complex thing. The Binet scale with its various modifications is far from being a satisfactory measuring implement, but it is remarkably good and has served well for purposes of sorting. It is not a fine measure of social fitness nor of industrial capacity but for practical purposes a classification of this type is most important. In the Vineland school such tests are being worked out with a considerable measure of success.

The classification and appropriate training of the subnormal is of immense importance to society, for they do not improve with age. A recent survey of misfit adults in one of our states revealed the same one per cent. or so belonging to the group of the largely helpless but not harmless, of those needing direction and supervision in conduct for life. Fortunately, educators are waking up to the fact that the capacity for profiting by public school instruc-

tion is very limited in subnormal children and that efforts to carry them with the average child are wasted, while the normal child suffers from the drag of these unfortunates. Special schools are being established with special emphasis upon manual training.

From a strictly medical point of view the fate of these children after leaving school is of the greatest importance, since at least half the army of prostitutes is recruited from their ranks. Since even an appropriate education does not render them less dangerous from this viewpoint, the supervision of such persons beyond school age is of prime importance, though at present this is largely neglected by the state. And here, as in other human defects and diseases, prophylaxis comes first. Why should one or two out of a hundred of the population be moron, imbecile, idiot, or other menace to society? What defective breeding! And heredity tells at least half the tale.

THE DIFFERENTIAL DIAGNOSIS OF INVOLUNTARY MOVEMENTS IN NERVOUS AFFECTIONS¹

A fact not perhaps generally known, is that syringomyelia may give rise to involuntary movements at its onset. The diagnosis is difficult because it is the very commencement of the disease and at this time frequently the only symptom is that of involuntary movements, either in the form of tremor, jerks or choreiform movements. These disturbances may lead to the erroneous diagnosis of chorea, myoclonia or some other type of tremor, the diagnosis of syringomyelia not being considered.

The chorea of pregnancy is usually observed in young primiparæ and a history of chorea in the early life of the patient is not uncommon. The abnormal movements usually appear during the first half of pregnancy and the symptomatology is that of an ordinary Sydenham's chorea. However, the intensity of the phenomena is more marked and chorea of pregnancy is serious. There are almost invariably unquestionable evidences of an acute psychosis, with intellectual failure, restlessness and maniacal excitement. During labor the involuntary movements increase in intensity, but this type of chorea usually subsides after labor and finally disappears.

Chronic chorea is exceptional in adults. The motor syndrome is much the same as in Sydenham's chorea, but the movements are slower and usually

less extensive. Generally they begin in the face, then extend to the upper limbs and only become general little by little. The influence of the will is much greater and causes an arrest or a momentary diminution of the involuntary gesticulations when intentional movements are made. Very distinct mental disturbances likewise exist; a weakening of both intelligence and memory which may even reach dementia and almost complete intellectual decay, all of which may occur early in the process at the same time as the motor disorders and sometimes even before the latter. Sensory disturbances are usually absent in chronic chorea. Dubini's chorea is a pseudochorea, characterized by rapid, instantaneous jerks. The principal element in the clinical evolution of this affection is the intermittent convulsive paroxysms followed by hemiparetic manifestations, but not generalized from the onset. Usually there are at first some local monoplegic convulsions and then progressively—requiring several weeks only—the convulsive state becomes general, as well as the paretic condition. It would seem that there is the same diffusion of the disorder as in the epileptic convulsive states whose onset presents the Jacksonian type and which after several apoplectic attacks transforms into a generalized epilepsy. Unquestionably, this process is a chorea symptomatic of some cerebral lesion as yet not clear either as to its site or its nature. Bergeron's chorea occurs between the age of six and twelve years and is probably a manifestation of hysteria.

Under the heading of myoclonia, Vanlair includes a certain number of more or less permanent morbid states characterized by sudden, incoordinated contractions, rhythmical or arrhythmical, rapid in succession, aborted or followed by an effective displacement, always occurring in the same parts and resulting from the alternation between the action and relaxation of certain muscles, multiple paramyoclonus develops insidiously or more rarely suddenly, the convulsions being usually clonic, sudden, involuntary and without displacement excepting when the jerks are severe. These convulsions diminish when the patient stands, increase when he is lying down, but cease during sleep. The will also controls them to a marked degree. There is no motor incoordination, no amyotrophy or mechanical or electrical changes in the muscles. Neither are there any sensory, vasomotor, secretory or psychic disturbances.

Athetotic movements of the fingers, sometimes also of the toes, are involuntary movements occurring especially around the metacarpal and metatarsophalangeal joints, the fingers passing successively from flexion to extension and from abduction to

adduction with remarkable slowness and extent. This may be the only symptom present or it may be accompanied by various motor disturbances—chorea, spasms—which modify the symptomatic picture. Athetosis offers two distinct types; hemiathetosis and bilateral athetosis. Anesthesia and sensory disturbances are absent, but permanent intellectual disorders often occur which may reach the state of idiocy. Symptomatic tremors—toxic, hysteric or idiopathic, sclerosis *en plaques*—hardly resemble athetotic tremors which disturb the health and normal functions of the organs.

An intention tremor is a characteristic symptom of sclerosis *en plaques* and confusion with Parkinson's disease is not possible. The tremor of paralysis agitans is in reality a permanent one which tends to improve or disappear under the control of the will or during intentional movement. Mercurial tremor is also intentional but disappears with rest.

PHYSICIAN AUTHORS: JOHN KEATS.

This is the centenary year of the death of one of England's greatest poets—John Keats, who died of consumption in Rome on February 23, 1821, before he had reached the age of twenty-six and before he had attained the peak of possible development as a poet. The anniversary has occasioned many expressions of regret for what might have been had Keats lived out a normal span of life. Taking their cue from Tennyson, his greatest disciple, who repeatedly said that had Keats lived he might possibly have been the greatest English poet after Shakespeare, critics now are agreed that Keats gave every promise of ranking with Shakespeare, Homer and Dante. But though he was cut down at the beginning of his career, Keats was, as J. C. Squire points out, "a prodigy unparalleled for the volume of masterly early achievement." He left us the immortal *Odes* and such treasures as *St. Agnes Eve*, *Lamia*, *Isabella* and *Endymion*, and a tidy quantity of the loveliest lyrical poetry the world has ever seen. The estimate of Keats's poetry today is not what it was when he died, for his genius was not generally recognized until long after his death. His poems were unmercifully criticized by the reviewers of his day, particularly those of *Blackwood's Magazine* and the *Quarterly Review*. They advised the poet, when he abandoned the practice of medicine, to "stick to your ointments and plasters and pills" and *Blackwood's* noted his death briefly as that of "a young man who had left a decent calling for the melancholy trade of Cockney-poetry." Since that time, however, Keats's reputation has steadily grown. All critics are now ready to proclaim his greatness and

the small circle of admirers of a century ago now embraces everyone who has any love or appreciation of poetry.

Although Keats became a full-fledged surgeon, his heart never was in the work and the Muse soon won him for her very own. He was not temperamentally fitted for the practice of medicine and surgery. His biographers tell us he never was able to concentrate on his surgical work, and, indeed, we have it direct from Keats himself that his mind was likely to wander, even while he was performing operations. "My last operation," he once told Charles Armitage Brown, who accompanied him on a walking tour of Scotland, "was the opening of a man's temporal artery. I did it with the utmost nicety, but, reflecting on what passed through my mind at the time, my dexterity seemed a miracle, and I never took up the lancet again." His desertion of the profession at least showed a scrupulous sense of responsibility to his patients. The trouble seems to have been that Keats was forced into the profession at too early an age, without being consulted in the matter, or at least before he was prepared to make an intelligent decision as to what lifework he wanted to pursue. He was only fifteen when his guardian (both his parents were then dead) bound him as an apprentice for five years to Dr. Thomas Hammond, a surgeon at Edmonton.

Even before that time, however, his passion for literature had been awakened and whenever he could spare time from his work he plunged into reading and translating. A translation of the *Æneid* was one of his achievements during this period. Once a week or oftener he used to walk to the village of Enfield, where the family had resided up to the time of the death of his mother a few months before, to visit his friend, Charles Cowden Clarke, the son of his former teacher. Cowden Clarke fed his hunger for literature, by discussing books with him and lending him volumes to read. One of these was Spenser's *Fairie Queene*, which had such stimulating effect on his imagination that he set himself to imitate it and was delighted to find that he could do so with success. Keats's first poem was his *Imitation of Spenser*. His genius thus awakened, Keats continued to compose poetry and the responsibilities of surgery became a secondary matter in his thoughts.

His biographers are silent as to why Keats did not finish out his apprenticeship with Dr. Hammond, but no doubt his absorption in poetry had more to do with it than anything else. It is likely Dr. Hammond lost his temper because of Keats's indifference to the tasks set before him, and so, along toward the end of the fourth year, they parted company,

with the surgeon making no effort to hold Keats to his indenture. It may be assumed that this parting was preceded by a more or less heated controversy, for Keats mentions in a letter that he "shook his fist at old Hammond." But Keats was not yet ready to abandon surgery; he was not yet sure of himself as a poet. What little he had written had not been shown to anyone, not even to his friend Clarke. He had learned much during his apprenticeship and wanted to learn more, and so went to London to continue his studies in the surgical school operated jointly by St. Thomas's and Guy's Hospitals. In London, through Clarke, he met Leigh Hunt, Shelley, and other literary lights and his poetical ambitions were further stimulated. "He gave way gradually to his growing passion for poetry," we are told, and gained a reputation among fellow students as "a cheerful, crochety rhymster," much given to writing verses in his friends' notebooks. Despite this his student notebooks show that he was not lax or inaccurate as a student, says Sir Sidney Colvin in his *Life of Keats*. The only signs of a wandering mind occur on the margins of one or two pages that contain drawings of flowers. But the lecture notes themselves are full and close and indicate that he listened with an accurate and attentive mind:

"Poetry had become his chief interest," says Colvin, "but it is clear, at the same time, that he attended the hospitals and did his work regularly, acquiring a fairly solid knowledge, both theoretical and practical, of the rudiments of the medical and surgical science, so that he always afterwards was able to speak on such subjects with a certain mastery. On July 26, 1815, he passed with ease and credit his examination as a licentiate at Apothecaries Hall, and was appointed a dresser at Guy's Hospital on March 3, 1816, and the operations he performed or assisted in are said to have proved him no bungler. But his heart was not in the work. He could not find in the scientific part of it a satisfactory occupation for his thoughts; he knew nothing of that passion of philosophical curiosity in the mechanism and mysteries of the human frame which by turns attracted Coleridge and Shelley to the study of medicine. The practical responsibilities of the profession at the same time weighed upon him and he was conscious of a kind of absent, easy wonder at his own skill. Voices and visions he could not resist were luring his spirit along other paths, and once when Cowden Clarke asked him about his prospects and feelings in regard to his profession he frankly declared his own sense of his unfitness for it, with reasons such as this: 'The other day, during the lecture, there came a sunbeam into the room, and

with it a whole troop of creatures floating in the ray; and I was off with them to Oberon and fairyland.'"

Keats definitely abandoned surgery in the winter of 1816-17, and his first volume, *Poems by John Keats*, appeared the following spring. But though he hated the idea of practice, evidently he did not feel himself unqualified for it so far as knowledge was concerned. It is said he was always ready to speak or act with authority in cases of illness or emergency.

OCULAR TUBERCULIDES

Tschoumakova in his work on attenuated tuberculosis of the eye, concludes by saying that these processes offer characteristic signs of Dor's tuberculides. The ocular tuberculides comprise phlyctenular keratitis, parenchymatous keratitis and iritis of a tuberculous nature. It should be recalled that they are encountered in tuberculous subjects, those with bacillary antecedents, or in patients who do not appear to have Koch's bacilli by guineapig inoculation, but give a positive tuberculin reaction fairly constantly. Affecting the disseminated eruptive type, they are benign, with a tendency to spontaneous recovery and appear in crops. For Dor, of Lyons, subjects offering these processes react to tuberculin; their sera gives Arloing and Courmont's reaction—agglutination of cultures of tubercle bacilli at 1:10—and when injected subcutaneously into the guineapig causes a rise in temperature. Tuberculides are not admitted by all observers and various theories explaining the mechanism of the bacillary infection have given rise to prolonged discussion. There are two principal theories to be considered, the oldest being the toxic theory of Hallopeau and, later, Boeck.

Wishing to explain the creating of nonspecific lesions without typical tubercles, soluble tuberculous toxins, elaborated in some small distant focus, either visceral or lymphatic, have been involved. Brought by the blood, these toxins are supposed to irritate the tissues directly or by the intermediary of the trophic nerves. Hence, absence of bacilli and specific pathological lesions, the torpor of the process and its indefinite duration or frequent recurrences, the bacillary focus continuing to elaborate new outputs of toxins. But Koch's bacillus possesses other toxins than the diffusible ones and Auclair's researches have shown that they act especially by the adherent toxins—etherobacillin or chloroformobacillin, nondiffusible poisons which necessitate the presence of the bacillus at the site of the lesion.

The second theory—that of Haury and Darier—is based upon the presence of Koch's bacillus in

certain lesions and positive inoculations, however extremely rare. The local action of the bacilli has given rise to three hypotheses: bacilli belonging to special strains, dead or attenuated bacilli, and rare virulent bacilli.

The theory of special strains of bacilli maintained by Hallopeau in the case of erythematous lupus, supposes mildly virulent attenuated strains and is based upon the special clinical evolution of these atypical tubercloses. As a reason, those supporting this theory state that it is difficult to conceive that ordinary bacilli can create lesions differing so greatly from typical follicular lesions. But patients presenting ocular lesions included among tuberculides usually offer other foci of visceral tuberculosis created by the ordinary bacillus and it seems strange that a patient should be infected by several strains of bacilli at the same time. Consequently the two following theories seem more likely.

The theory of very attenuated or dead bacilli due to Haury, and later adopted by Darier and Jadassohn, asserts that the tuberculides are the result of emboli composed of bacilli very attenuated and extremely low in virulence, coming to the skin by the blood, which promptly die in the struggle against the phagocytic or bactericidal reaction of the invaded tissues. The bacilli reach the skin still capable of setting up a temporary local reaction or even small foci of necrosis, but they die or disappear rather quickly, hence spontaneous cure or non-inoculability of the lesions. The tuberculides are consequently cutaneous tubercloses originating in the blood. This theory based on the benignity of tuberculides explains the rarity of the bacilli in them and their accidental presence, as well as the inconstancy of positive inoculations.

The third theory, due to Gougerot, is that of rare but virulent bacilli. These come from some visceral or lymphatic focus and reaching the skin are immediately surrounded by a defensive reaction. The tissue reaction may be intense precisely because the bacilli are sufficiently virulent to set up a sharp cell proliferation and an afflux of leucocytes, but this nodular reaction is not follicular because the bacilli are few and being isolated their toxic action is not sufficient to create a tubercle. If a biopsy is done at this time, a rare bacillus may be found in the stained sections but only exceptionally. On account of this sharp cutaneous reaction the bacilli cannot multiply—they remain isolated.

The phagocytosis soon attenuates and destroys them. They remain living for a certain time and die at the end of the defensive tissue reaction. A biopsy at this time reveals no bacilli in the sections and guineapig inoculation is negative. The bacilli

once destroyed and absorbed, the lesion heals spontaneously.

In favor of the rarity of bacilli, the extreme difficulty of staining them in the sections may be mentioned and the impossibility of detecting them in the sections although occasionally a positive inoculation may be obtained. The small number of bacilli certainly plays the most important part but slow toxic impregnation of the organism unquestionably has an influence, while the nature of the soil is of highest import. Diminution of organic resistance has an unfavorable action in the development of tuberculides, while the contrary is true in favoring their development. And Gougerot insists on the resistant soil slowly intoxicated and tuberculinized as being one of the most powerful factors in the development of tuberculides with rare virulent bacilli. Undoubtedly, this theory seems more seductive and likely than the others, but the question is not yet solved, so that it is still uncertain whether phlyctenular keratitis can be regarded as a tuberculide. All that can be said for the present is the frequency of this lesion in tuberculous subjects.

MENTAL AGE OF ADULTS.

The increasing use of group intelligence tests should reduce the adult vanity to zero if it is carried far enough. Several years ago the average mental age of adults was said by psychologists to be sixteen years. Now comes a writer in the *Journal of Applied Psychology* and declares that it is only thirteen years. Not only that, but he declares that "the growth of general intelligence is found to be practically complete on the average by thirteen years of age, and is not on the average thereafter exceeded." This, he adds, applies strictly to the level of intelligence or degree of brightness, and not to "intelligence plus maturity, experience and acquisitions." His conclusions are based on the application of group intelligence tests to about 1,500,000 soldiers, 500 school children, 500 delinquent boys, and 250 feebleminded individuals.

News Items.

Philippine Government Studies New York Health Methods.—Dr. Juan Fernando, of the Philippine Health Service, during the last six months, has made an intensive study of the methods in use in the New York State Department of Health.

Director of Tuberculosis Division Resigns.—Dr. Malcolm F. Lent, director of the division of tuberculosis of the New York State Department of Health, tendered his resignation, which became effective on July 1st, in order to practise his specialty at Saranac Lake, N. Y. Dr. Lent was formerly superintendent of Stony Wold Tuberculosis Sanatorium at Lake Kushaqua, N. Y.

A Bust of Morton for the Hall of Fame.—At the annual dinner of the American Anesthetists held in Boston during A. M. A. week, Dr. S. Adolphus Knopf said it would be a proud privilege for the Associated Anesthetists to place a bronze bust of Morton in the niche assigned him by the electors to the Hall of Fame. This is to be done on October 16th.

1,900,000 Tuberculosis Invalids in France.—Dr. Baillon, laureate of the Faculty of Medicine of Paris, has come to America to reveal how serious the tuberculosis peril is in France. He is president of the Franco-American Committee of Fight Against Tuberculosis and is seeking members. Dr. Baillon says there are 1,900,000 cases of tuberculosis in France and not more than 10,000 beds available for the invalids. The number of deaths has reached 20,000 a year.

Scientific Temperance Federation Library.—A valuable library service of scientific works and references dealing with alcohol, owned by the Scientific Temperance Federation of Boston, is open to students and physicians. At the annual meeting of the Federation held June 23rd, a number of prominent men were elected as officers. Among the honorary vice-presidents are Dr. Richard C. Cabot, Dr. Haven Emerson, Dr. W. A. Evans, and Dr. Harvey W. Wiley.

\$35,000 to New York University.—The Rockefeller Foundation announces a contribution of \$35,000 to New York University to provide a clinic in the new building which the university is erecting adjacent to the university and to Bellevue Hospital Medical College. The gift supplements a contribution made last year by the General Education Board to the endowment fund of \$350,000. The new building will house a branch laboratory of the New York State Department of Health.

State Health Department Uses Social Hygiene Field Car.—The Venereal Disease Division of the New York State Health Department has secured the use of the social hygiene field car. It will be sent to counties where the home bureau agent makes a request for its use and agrees to arrange in advance for at least one lecture for men each day it is in the county. Lecturers will be furnished by the division. Ten counties have already requested the use of the car.

Public Health Institute Postponed.—The proposed Public Health institute which the United States Public Health Service contemplated holding in Washington, D. C., during the fall of 1921, has been indefinitely postponed. This action has been decided upon after several conferences between officers of the Service and officers of the American Public Health Association. The fiftieth annual meeting of the American Public Health Association is to be held in New York, November 14 to 18, 1921. Several other activities are planned by the association in connection with their semicentennial meeting, and it is at the request of the American Public Health Association that the service institute for next fall has been abandoned. The Service hopes that it will be possible to arrange to hold a similar institute in Washington during the spring or fall of 1922.

Cholera Spreading in European Russia.—Asiatic cholera is spreading rapidly in the whole of European Russia. There were six thousand cases reported up to June 25th. Petrograd and Moscow have become infected and the disease is spreading quickly and being propagated by the unusually hot weather.

Cancer Days in Pennsylvania.—Dr. William Pomp Walker, of Bethlehem, arranged for a cancer day for Northampton and Leigh counties on Friday, May 20th. A committee of arrangements was appointed, made up of the medical societies of these two counties, the Lehigh Valley Homeopathic Medical Society and the Pennsylvania Eclectic Medical Society. Harrisburg is planning a cancer day for September 6th.

American Gynecological Society.—At the annual meeting of the American Gynecological Society held at Swampscott, Mass., June 2d, 3d, and 4th, under the presidency of Dr. W. W. Chipman, of Montreal, the following officers were elected for the ensuing year: President, Dr. George Gray Ward, Jr., of New York; first vice-president, Dr. Barton Cooke Hirst, of Philadelphia; second vice-president, Dr. Walter P. Manton, of Detroit; secretary, Dr. Arthur H. Curtis, of Chicago; treasurer, Dr. Brooke M. Anspach, of Philadelphia. Other members of the council are Dr. Walter W. Chipman, of Montreal; Dr. Dougal Bissell, of New York; Dr. Fred L. Adair, of Minneapolis. The next meeting of the society will be held at Washington, D. C., on May 1, 2 and 3, 1922.

Personal.—Dr. G. Canby Robinson has been appointed to succeed temporarily Dr. William S. Thayer as professor of medicine at the Johns Hopkins Medical School and physician in chief of the Johns Hopkins Hospital.

Dr. Calvin H. Goddard has been appointed second assistant to the director of Johns Hopkins Hospital, succeeding Dr. A. J. Lomas.

Dr. Livingston Farrand, chairman of the central committee of the American Red Cross, formerly professor of anthropology at Columbia and former president of the University of Colorado, has been elected president of Cornell University.

Dr. John J. Erwin has been appointed superintendent of Mercy Hospital, Baltimore, taking charge of the hospital on July 1st.

Dr. Lee K. Frankel, vice-president of the Metropolitan Life Insurance Company of New York, has assumed personal charge of the welfare bureau set up in the Post Office Department to improve the working conditions of the 300,000 men and women postal workers.

Dr. Alexis Carrel has been elected a national associate of the Academy of Medicine of Paris. Under the rules of the academy, there may be only twenty national associates, all of whom have heretofore been residents of France.

Dr. Thomas W. Salmon has been appointed professor of psychiatry at the College of Physicians and Surgeons and has resigned from the staff of the Rockefeller Foundation. Both appointment and resignation took effect on July 1st. Dr. Salmon will continue to serve as the medical director of the National Committee for Mental Hygiene.

Died.

ABBOTT.—In Chicago, Ill., on Monday, July 4th, Dr. Wallace Calvin Abbott, aged sixty-three years.

BECHTOLD.—In Belleville, Ill., on Friday, June 17th, Dr. Louis J. Bechtold, aged seventy-three years.

BURR.—In Williamson, N. Y., on Sunday, June 12th, Dr. Henry Newton Burr, aged eighty-three years.

BUTLER.—In Buffalo, N. Y., on Wednesday, June 22nd, Dr. George Frank Butler, of Wilmette, Ill., aged sixty-four years.

DICKIE.—In Bremen, Ga., on Sunday, June 26th, Dr. James R. Dickie, aged thirty-six years.

DUNBAR.—In Manchester, N. H., on Sunday, June 19th, Dr. Eugene B. Dunbar, aged sixty-three years.

EARLE.—In Greenville, S. C., on Wednesday, June 29th, Dr. Thomas T. Earle, aged seventy-six years.

ELY.—In Ainsworth, Neb., on Thursday, June 23rd, Dr. William B. Ely, aged seventy-nine years.

FIELD.—In Elroy, Wis., on Wednesday, June 22nd, Dr. Ferdinand T. Field, aged sixty-nine years.

FINCH.—In New York, on Tuesday, June 21st, Dr. Sarah E. Finch, of Sound Beach, Conn., aged thirty-nine years.

GORDON.—In Portland, Me., on Wednesday, June 22nd, Dr. Seth C. Gordon, aged ninety-one.

GUY.—In Greenc, N. Y., on Tuesday, June 21st, Dr. Clement North Guy, aged eighty-one years.

HARTWELL.—In Philadelphia, Pa., on Tuesday, June 21st, Dr. John Henry Hartwell, aged forty-eight years.

HEALY.—In Denver, Col., on Friday, June 24th, Dr. Michael D. Healy, aged forty years.

HUNT.—In Little Falls, N. Y., on Saturday, June 25th, Dr. Ward E. Hunt, aged fifty-one years.

INGERSOLL.—In Canandaigua, N. Y., on Sunday, July 3rd, Dr. Joel M. Ingersoll, aged sixty-four years.

JENKINS.—In New York, on Saturday, June 25th, Dr. William T. Jenkins, aged sixty-five years.

JOHNSON.—In Toronto, Canada, on Thursday, June 9th, Dr. Arthur Jukes Johnson, aged seventy-two years.

JOHNSON.—In Assumption, Ill., on Friday, June 10th, Dr. Robert Wesley Johnson, aged seventy-two years.

KALISH.—In New York, on Monday, June 20th, Dr. Richard Kalish, aged sixty-seven years.

LACIAR.—In Bethlehem, Pa., on Monday, June 13th, Dr. Henry J. Laciari, aged sixty-three years.

LAIRD.—In Haverstraw, N. Y., on Friday, June 24th, Dr. Eugene B. Laird, aged sixty-four years.

MOON.—In Cooperstown, N. Y., on Tuesday, June 28th, Dr. John Henry Moon, aged seventy-two years.

NIGHTINGALE.—In Philadelphia, Pa., on Thursday, June 23rd, Dr. Henry B. Nightingale, aged sixty-six years.

OLIVER.—In Chula Vista, Cal., on Friday, June 10th, Dr. Leonard Briggs Oliver, aged sixty-three years.

PARRY.—In Waynesburg, Pa., on Saturday, June 25th, Dr. William M. Parry, aged seventy-eight years.

POTTER.—In Rochester, N. Y., on Friday, July 1st, Dr. Ezra B. Potter, aged seventy-two years.

ROSE.—In Albany, N. Y., on Wednesday, June 22nd, Dr. Edgar M. Rose, of New York, aged thirty-seven years.

SLIGH.—In Long Beach, Cal., on Wednesday, June 8th, Dr. James Sligh, of Montana, aged seventy-six years.

STALLMAN.—In Irondequoit Bay, N. Y., on Thursday, June 30th, Dr. George B. Stallman, of Camp Dix, N. J., aged forty-four years.

STATON.—In Tarboro, N. C., on Saturday, July 2nd, Dr. Lycurgus L. Staton, aged seventy-two years.

THOMAS.—In Philadelphia, Pa., on Tuesday, June 28th, Dr. Charles Hermon Thomas, aged eighty-two years.

TOWNE.—In Lake Champlain, N. Y., on Saturday, June 18th, Dr. Everett S. Towne, of Burlington, Vt., aged thirty-six years.

VANDERSLICE.—In Philadelphia, Pa., on Tuesday, June 28th, Dr. Edward S. Vanderslice, aged seventy-seven years.

WARD.—In Cohoes, N. Y., on Saturday, June 25th, Dr. Bela J. Ward, aged sixty-three years.

WINCHELL.—In Brooklyn, N. Y., on Saturday, June 18th, Dr. Walter Bernard Winchell, aged sixty-three years.

LONDON LETTER

*(From our own correspondent.)**Obstetrical and Gynecological Unit of the Royal Free Hospital, London—X Ray Dangers—Conference on National Health—Dangers of Radium—Professional Secrecy—Infection with Syphilis from the Mother—Obituary.*

LONDON, May 30, 1921.

Care and treatment of the sick and injured has existed in all ages. In the early centuries of Christian civilization hospitals were founded and were wholly in the hands of the religious orders. In those days monks and nuns, especially those of certain orders, were well versed in the application of simples, they had a somewhat elementary knowledge of drugs and pharmacology, and knew how to bind up wounds. It was not until the reign of Edward VI that the charter of the Barber Surgeons was granted in England (1461). The first medical registration act followed in 1511 and the Royal College of Physicians was founded, in the reign of Henry VIII in 1518. Since that time medical knowledge and education in Great Britain has gone forward fitfully but the passing of the Medical Act of 1858 marks a distinct step in the progress of modern medicine and teaching.

Medical education in Great Britain was carried on for many years under a system of apprenticeship which had developed from the day when young men were apprenticed to physicians and surgeons who had made a name for themselves either in hospital work or private practice. This system was developed or changed later on into that system now known when all medical students become clerks and dressers to the members of the hospital staff and are taught their clinical work in the wards of a general hospital recognized by the general medical council (a general hospital being a hospital where men, women and children are treated). The physicians and surgeons on the staffs of these general hospitals (there are twelve in London) were usually those who had shown themselves to be excellent clinicians and surgeons, and part of their duties, a very important part, was the teaching and training of the medical students. In many cases the physicians and surgeons were thoroughly able teachers and in some cases did much good and original work in research. It can, however, be readily understood that a capable physician or surgeon had many calls on his time for private work and that also that being a good physician or surgeon did not necessarily mean that he was a good teacher. Moreover, the work in medicine and surgery has become more and more specialized as time went on and pathology now occupies a large place in the education of all medical students.

In 1913 the idea of "units" for the teaching of medicine, surgery, obstetrics and gynecology was first brought forward in Great Britain in the Haldane Commission on University teaching, but owing to the war the development of teaching on these lines was held in abeyance for some years. The underlying plan of a unit, or team work, is that a director and two or more assistants should have a certain numbers of beds, sixty to one hundred, under their control, and that they should devote the whole of their time to the care of these patients,

the teaching of students and to research, the directors to be chosen for their known good work, their powers of imparting their knowledge to the students, and their interest in and capacity for research; and the assistants to be selected for the promise of developments along these lines they had exhibited since their qualification. Up to the present time only five of the twelve great teaching hospitals of London, to wit, St. Bartholomew, London, University College Hospital, St. Thomas's and the Royal Free Hospitals, have been recognized by the University Grants' Committee as eligible for the conduct of units and to which directors of units have been appointed by the Senate of the University of London. In the first four hospitals in this list units of medicine and surgery have been organized.

To the Royal Free Hospital has been accorded the honor of being the first hospital to be permitted to conduct a unit of obstetrics and gynecology. Hitherto the work in general hospitals in connection with obstetrics and gynecology has been under the care of various physicians, obstetricians and gynecologists, i. e., the antenatal work, the obstetric department of the hospital and in the district surrounding the hospital, the baby consultations and infant welfare department, the outpatients' department and wards for the diseases of women, and the department for venereal disease. This work is now coordinated in the unit of obstetrics and gynecology under the Director, Professor A. Louise McLroy, and her assistants who will follow the cases from the time they first come under observation and in this way a more thorough view of the history of disease will be obtained and the students will be enabled to observe and study the early stages of disease and its subsequent developments instead of coming across the case at different stages in different departments.

This system of unit teaching is in its infancy and the University Grants' Committee have provided in the first instance that it shall continue for a term of five years when it will be examined carefully in order to judge whether it has succeeded sufficiently to warrant its continuance. This system of education is necessarily very expensive, since the director and assistants are debarred from private practice, and could not be carried out without grants from the treasury supplemented by payments from the medical school, but if, as it is confidently believed, it will result in a much more comprehensive and vivid view of disease and lead to improved methods of prevention and treatment, it will be well worth the money expended upon it.

The Obstetrical and Gynecological Unit of the Royal Free Hospital School of Medicine for Women, University of London, has its headquarters at the Royal Free Hospital, Gray's Inn Road, London, E. C. It occupies the top floor of the new wing of the hospital building and consists of an obstetrical ward of twelve beds, with smaller wards for labor and isolation, etc.; adjoining it are three wards of twenty-six beds in all for gynecological cases with operating theatre, anesthetic and preparation rooms attached. At the further end of the wing is the teaching department, consisting of

an examination room for patients and demonstrations for students, a professor's room, assistant's clinical laboratory with secretary's room where inquiries are made as to the work of the department. A cloak room for the staff, and a suite of rooms for the residential obstetric surgeon completes the accommodation. Lectures are given to the students in the main lecture room downstairs. There is a branch of this hospital which is under the director of the unit and which accommodates twenty-six obstetric beds, a few venereal obstetrical cases being included. This hospital was given by the Duchess of Marlborough, nee Vanderbilt, and is situated in Endsleigh Street close by the main building. It is composed of small wards daintily furnished and is run on the lines of a nursing home. The patients in this department pay for their maintenance in hospital according to accommodation. It has labor wards, isolation, etc. The department at the Royal Free Hospital is being equipped for research work upon antenatal pathology and also upon the physiological processes connected with childbirth and pregnancy. Special researches will be made upon the economic questions in women's work, upon the influence of such upon the child, the influences of venereal and other toxic diseases in pregnancy.

An account of the Obstetrical and Gynecological Unit at the Royal Free Hospital would be incomplete without a sketch of the recently appointed director of this unit. Dr. A. Louise McIlroy is a distinguished graduate of Glasgow University, and has held important medical posts in the city of her birth. Almost at the outbreak of the war Dr. McIlroy volunteered for active service and joined the Scottish Medical Women's Contingent under the leadership of Dr. Elsie Inglis. While serving on all the fronts, with the exception of the Italian, by far the greater part of her work was done in the near Eastern theatre of war. At one time Dr. McIlroy was surgeon in charge of the British Hospital in Salonika, and when there she sent an extremely interesting paper which was published in the special war number of *American Medicine*, issued some two or three years ago. For some time before the end of the war and for a period after its close, Dr. McIlroy was the head of an obstetrical and gynecological hospital in Constantinople where she acquired a good deal of experience in the idiosyncrasies, if the term is applicable, of Eastern women in labor. Some of these experiences and her methods of treatment she related two months or so ago before the Obstetrical and Gynecological Section of the Royal Society of Medicine, London. Dr. Louise McIlroy was appointed recently in open competition director of the Obstetrical and Gynecological Unit at the Royal Free Hospital. A better choice could not have been made as Dr. McIlroy, in addition to her mental gifts and comprehensive and accurate knowledge of her special subject, is an excellent organizer, and despite the fact that the rôle of prophet is a thankless one, I venture to predict that not only will good work be done at the new Unit but that the original research there will result in discoveries that will immensely improve the practice of obstetrics. It is well known that at

the present time, this branch of surgery, especially in this country, is in a backward condition. There is room for great improvement and the establishment of the Unit under the direction of Dr. McIlroy is an obvious step in the right direction.

* * *

The death of Dr. Ironside Bruce, the radiologist to Charing Cross Hospital, presumably from the effects of constantly operating x rays, has again directed attention to the danger to which all are exposed who treat disease by x rays and radium. But the case of Dr. Bruce differs from that of the earlier operators of this form of treatment. The dangers then were chiefly those which were due to the overexposure of the skin of the operator to the radiations. The damage thus wrought frequently developed into malignant growths. The risk of such occurrences has been overcome to a large extent by the employment of appropriate protective measures. However, a new danger appears to have now exhibited itself since the use of more penetrating radiations. The result is, that in place of the ill effects being manifested on the surface, the deeper structures, particularly the blood forming cells, have been attacked. One of the manifestations is that form of anemia known as aplastic, to which condition Dr. Bruce fell a victim. This type of anemia appears to be intractable to treatment, leading to general weakness and in some cases to death. Still, it may be noted that anemia of this kind occurs also in those who have never been exposed to radiations. As for the precise manner in which aplastic anemia is brought about opinions vary. Although it has been proved in some cases to be due to the radiations themselves, the view is held that the production of nitrous acid in the air by the electric discharges may be a predisposing factor, one point is quite clear, namely that vitiated air brings about that state of fatigue, well known to x ray workers, especially in restricted spaces. The necessity for well ventilated departments is therefore patent.

Up to the present time it has not been possible to gauge what is a minimum safe dose to which operators may submit themselves, but researches in this direction now going on inspire the hope that this difficulty is not insurmountable. The danger to operators is a hidden one, as the collection of radium emanations by means of the somewhat complex apparatus now in use has a danger of its own. As a rule, no special sensation is produced by these radiations. Consequently, the danger is all the greater because it is almost completely hidden. The whole subject requires careful and systematic investigation. This much is plainly obvious, that the rapid development of the technic has rendered those protective measures already devised more or less obsolete, at any rate, they are not completely effective. Therefore, as said before, very extensive research is required in all branches of radiation work, and on the technical side, in particular. An Institute of Radiology has been suggested for this and there is no doubt whatever that it is greatly needed.

Radiologists here have been much handicapped by the absence of means for research on organized

and comprehensive lines. It is encouraging to learn that in order to meet this pressing need an effort is being made to obtain funds for an Institute of Radiology as a memorial to the late Sir James Mackenzie Davidson, a great pioneer of the science. While, of course, such an institute should be thoroughly equipped from the physical, biological and technical side, it may again be emphasized, that, owing to trade conditions, it is from the technical viewpoint that Great Britain has been more handicapped than any other country. The large electrical corporations in America and Germany have fostered the development of applied science and thus have been able to bring out new apparatus and technic.

According to an article contributed to the *Observer*, April 3, 1921, as a preliminary measure to the establishment of an Institute of Radiology, a committee of experts is being formed for the purpose of investigating methods of protection. But, as the writer of the article in question goes on to say, "The outcome of the work of this committee will be awaited with great interest; to be, however, of real use, any authoritative recommendations which may be made must be followed up by equally authoritative action." This advice is useful and to the point, as it appears to be becoming somewhat of a habit here for committees to be formed who spend a good deal of valuable time and money in investigation, write out a good and voluminous report and then the matter is shelved indefinitely. The subject of radiation is important and serious. Recently, much progress in this form of treating certain diseases has been made and its possibilities from the therapeutic point of view seem to be almost illimitable. No effort should be spared not only to render the x ray and radium treatment more and more effective but safe to the operator. It has been shown to be safe so far as the patient is concerned, but until it has been made safe for the operator also, such treatment cannot be deemed really effective. There is little doubt that carefully conducted investigations done under favorable conditions would result in the evolution and development of measures which would safeguard the operator. An Institute of Radiology would provide the means for carrying out researches under the best possible conditions, and it is to be hoped that an institute of this kind will be founded in Great Britain in a reasonably short space of time.

* * *

A conference on national health was held on April 2, 1921, at the Central Hall, Westminster, London, under the auspices of the Faculty of Insurance, Ltd. Incidentally, it may be mentioned that Dr. Christopher Addison has retired from the post of minister of health, and that Sir Alfred Mond has been appointed in his place. Sir Kingsley Wood, M. P., speaking at the conference, said in part that the new minister of health had many qualities of eminence, notably that of being a keen administrator and a capable business man. He had been interested in health work in connection with hospital administration, and on the housing side of their work he would prove a capable and popular minister.

Reviewing some of the points of health administration, Sir Kingsley Wood remarked that during the last two years the financial situation had had a very serious effect upon national health plans. A matter which would have to be considered by every insurance worker in the future would be how far they could, under the present condition of affairs, hope to extend many of their services.

The trend of the deathrate in England and Wales was steadily downward, and the decline had taken place in all ages. Recently this improvement had extended to the middle years of life. During the first twenty years of the present century there had been a remarkable fall in the infant mortality rate. In no small measure the progress that had been made was undoubtedly due to the continual steps that were taken to combat disease and death. In 1919 forty-two per cent. of the total deaths took place under forty-five years of age, and this was surely a matter within human control. In England and Wales there were at least a million and a half people constantly on the sick list; over 13,000,000 weeks were lost in England on an average every year through sickness, and on that account the nation lost every year the equivalent of the work of 260,000 persons of the industrial classes alone. The death rate of women in childbirth remained approximately what it was twenty-five years ago, and 3,000 mothers were so lost every year, a mortality which was almost entirely preventable. Sixty thousand infants were lost every year. These were some of the vital problems which confronted the nation, and they were of exceptional difficulty, having regard to the state today of the financial resources of the country. Progress, commercial and otherwise, depended largely upon the nation's health. Nothing was so wasteful and extravagant as preventable unhealthy conditions; nothing was so economical as carefully expended money in avoiding them.

Few people realized that the great influenza scourge destroyed more human life in a few months than the European war in five years. In forty-six weeks, from June, 1918, to May, 1919, over 150,000 deaths were attributed to this disease alone in England and Wales. Who could count what the financial loss was to the community? While the Ministry of Health had now to look twice at every penny that was spent, he had no hesitation in saying that they must continue their work, at the same time having regard to the needs and difficulties of the time.

Sir Walter Kinnear, controller of national health insurance, who spoke on Valuations of Approved Societies, paid a high tribute to Dr. Addison, who, he said, had the entire confidence of the approved societies, and carried with him to his new appointment the regard of all who came into personal contact with him. Since the National Health Insurance Act was passed no less than £65,000,000 had been paid away in cash benefits, £53,000,000 had been spent in medical and sanatorium treatment, and £83,000,000 had been accumulated in invested funds. Now that the war clouds were lifting it was not unnatural to turn to the National Health Insurance Act and ask what the valuations of the

approved societies were revealing. The valuation results in respect of nearly 7,000 societies and branches, out of the total number of 10,300, had now been issued and showed an aggregate surplus over liabilities of about £6,500,000 and a disposal surplus of nearly £4,000,000. These figures related to 5,500,000 insured persons.

The completed valuation results indicated that only eight per cent. of the societies and branches had no disposable surplus, and only three cases had yet emerged in which resort would have to be made to the central fund. As to what the societies intended to do with this large surplus, Sir Walter Kinnear said that, in view of the high cost of living, no doubt the inclination would be to increase the cash benefits, but there was a growing feeling among approved societies that the prevention and eradication of disease was just as much their function as its palliation. As the maintenance of the voluntary system of hospital management is desirable in the public interest, it would be regrettable if the exigencies of the situation compelled the hospitals to close their doors to insured persons. Sir Walter Kinnear said he understood that a number of hospitals are prepared to accept members of approved societies on the payment of something like fifty per cent. of the actual cost, and, in his opinion, this was an offer which the societies ought carefully to consider. A weekly payment toward the cost of each individual member might be made, or a pooling system adopted, whereby in return for a quarterly or yearly subscription to a central body, hospital services reasonably commensurate with the amount of the subscription could be obtained.

Sir Thomas Neill, Consultative Council on Health Insurance Approved Societies, urged the claims of voluntary hospitals for support from approved societies, pointing out that to these hospitals all were indebted for the medical knowledge possessed. Of the patients treated a considerable proportion were members of societies, and, inasmuch as the hospitals cured these people of their ailments, they saved the societies large sums which otherwise would have to be paid in sickness benefit.

* * *

At a meeting of the Section for the Study of Disease in Children of the Royal Society of Medicine, held in the building of the society on March 16, 1921, Mr. J. E. R. McDonagh said that if a woman contracted syphilis before the fifth month of pregnancy the child always contracted the disease; if she became syphilitic during the sixth and seventh months the child was affected by congenital syphilis in about half the cases, and, if during the eighth and ninth month, the child escaped.

* * *

The French Academy of Medicine has recently appointed a committee to frame a list of the measures of precaution to be employed to safeguard the use of radium. The decision followed the reading of a paper by Professor Bordier, of the University of Lyons, who declared that the dangers incurred by those manipulating radium are greater by far than those faced by x ray operators. The com-

mittee will include Doctors Bécélère, Delbet, Siredey, Broca, Quénu, and Martin.

* * *

The Council of the Royal College of Surgeons in Ireland has passed the following resolution: "The Council is of the opinion that it is contrary to the public interest that medical men should break their professional tradition and, without the consent of the patient, disclose information which they have obtained in the discharge of their professional duties. If any instance is reported to the Council in which one of the Fellows or Licentiates of the College is pressed to break confidence, such specific case will be considered by the Council and representations made to the authorities if such be thought necessary."

* * *

On Tuesday, March 29, 1921, a notable figure in the British medical world passed away. Reference is made to Dr. Robert Murray Leslie, 143 Harley Street, London, W., who died at the early age of fifty-four. Dr. Leslie was one of the most distinguished students who ever passed through the medical course at Edinburgh University. He took his degree of M. A. with the highest honors, B. Sc., M. B., M. Ch., first of the first class. When he obtained the degree of Bachelor of Science he was awarded the Sir Edward Baxter Scholarship as the most "eminent science graduate" of the year. He was awarded the Ettles Scholarship, which is given to the most distinguished medical graduate of the year, and also obtained the Stark Scholarship in Clinical Medicine. He was likewise awarded the premier University Medals in Practice of Physic and Obstetric Medicine. He held the post of House Physician at Edinburgh Royal Infirmary, and when he came to London was made House Physician at the Brompton Chest Hospital. In 1894 he was appointed Assistant Physician to the Royal Hospital for Diseases of the Chest, and after doing good work there for twenty-six years retired a few months ago, being then Senior Physician. He was also physician to the Prince of Wales's General Hospital at Tottenham, near London. Dr. Leslie was one of the founders of the North-East London Post-Graduate College, Tottenham, and of the North-East London Clinical Society. He was Fellow of several learned societies, and in July, 1896, was elected an officer of the French Academy.

Dr. Leslie was an exceptionally able man from all points of view. He was an excellent lecturer, presenting his subject in a clear and vivid manner, and as a writer, besides being logical and cogent, possessed literary charm and distinction. Among his writings may be mentioned the article on hemoptysis in the *Encyclopedia Medica*, 1900, and shortly before his death he had completed an important work on Pneumonia and Its Modern Treatment for the *Oxford Medical Press*. He contributed many papers to medical and scientific journals.

In private life Dr. Leslie was liked universally. He was of a kind disposition, and he spared neither time nor money to aid those he knew and liked. No man of the British medical profession will be more greatly mourned or more keenly missed than Robert Murray Leslie.

Book Reviews

THE AMERICAN SCHOOL OF PSYCHIATRY.

Foundations of Psychiatry. By WILLIAM A. WHITE, M. D.
With an Introduction by Dr. STEWART PATON. Nervous
and Mental Disease Monograph Series No. 32. New
York and Washington: Nervous and Mental Disease Pub-
lishing Company, 1921. Pp. ix-136.

Dr. White has presented this monograph as an exposition of features of the American School of Psychiatry. He has done more than this and he has done less; the viewpoint will depend largely upon the reader. The so-called psychiatrist who flamboyantly declares that any examination of the unconscious is pernicious, and when it is attempted in young people is "criminal," will deny that the American school is represented, for is not this physician an American and does he not call himself a psychiatrist? But he has not been overlooked in this valuable little book of Dr. White's; he has been properly tabulated in the evolutionary scale of the development of psychiatry. He is the physician who knows every symptom of the neurotic and given enough of these he knows the name of the patient's disease. He will attempt to say if the patient can be cured or whether the condition is hopeless. This type of psychiatrist is content with archaic psychiatry. He best expresses his attitude by saying "if it was intended that certain things be placed in the unconscious, what right have we to bring these things to light?" What right did we have to dissect bodies? What right have we to cure neurotics or psychopaths if it was intended that they function mentally in a different fashion?

Now there are others who will say the monograph does more than the author modestly states. First it presents with marked clarity many of the tenets set forth by the more progressive psychopathologists; many of which have not been realized by workers in psychopathology on account of the highly condensed form in which they have been presented. Many of the terms are used constantly by psychopathologists, terms which can not be avoided if common ground is to be held, are so simplified in this monograph that for the first time many workers will be able to get an understanding of them.

One of the most important things that has been done for the first time, is the binding together of the salient features which have been developed by the various workers in the American field. Dr. White has shown how, in order to meet an effective need

due to environmental situations, the American school has worked out a more pragmatic, a more basic psychopathology than that of their European coworkers. Much courage was required, for the fundamental concepts as set down by Freud were so far-reaching and so basic that they startled the workers who found his teachings to be truths and workable. But it can safely be said that while American workers have added much to the primary principles of Freud they have followed him more closely than have many European workers, who by their labors have added less to the practical value of analysis. So far the workers in the American school have not attempted to enter the realm of metaphysics as have some of the British workers, nor the realm of theology as has been attempted by some of the Swiss school.

It is stated that the war was one of the factors causing a demarcation in the trend of the development of the various schools. This may have hastened the process, but it was bound to come, for the needs were not the same. It may be stated that neuroses and psychoses are the same the world over. This is true, but the factors causing the various conditionings are not the same here. The obstacles encountered are not the same. The mechanisms of repression and regression are the same. The patient always goes back to infantile archaic levels when he encounters an obstacle which his ego does not face or fight. For this reason we have been able to build on the foundations of Freud and for this reason the European workers will be able to utilize the findings of their

WILLIAM A. WHITE, M. D.,
Author of *Foundations of Psychiatry*.

American colleagues which here have been outlined.

White has enumerated the features emphasized by the American school as follows: 1. The unity of the organism as an energy system; 2, human behavior as a special problem of energy transformation and discharge; 3, structural organization as an instance of the phyletic synthesis of experience, with the nervous system as the chief agent in this organization; 4, the principle of action patterns of discharge as integral parts of the structural organization; 5, the conception that the symbol is a source and carrier of energy; 6, the abolition of the metaphysical distinction between mind and body; 7, the conception of the unconscious as a container of the phyletic history of the organization of the psyche in action pattern symbolization; 8, the importance of archaic symbols and their relationship to somatic as well as mental diseases; 9, the belief that organic disorders have their psychological as well as their

somatic symptomatology; 10, the belief that standards of conduct are an integral part of the action pattern symbolization and therefore must be included in the understanding and management of all medical and social problems.

This is an excellent résumé of the situation. White takes up each of these subjects in turn and handles them with the same clarity as his initial classification. He takes the matter up in historical progression and traces the development of psychiatry step by step. No clearer exposé of the phylogenetic and ontogenetic archaic background of the genus *Homo* has come to the notice of the reviewer.

Many monographs of great value have been published in this series, but nevertheless this, the last one of the series, is one of the most helpful to the medical man interested in human behavior and its queer twists and turns. It is intensely stimulating to the worker in psychopathology who has long looked for a book of this character and it is of real, practical value to the medical man. It presents a sound psychology and a profound philosophy.

SEX AND LIFE.

Sex and Life. By W. F. ROBIE, M. D., Superintendent of Pine Terrace, Baldwinville, Mass. Boston: Richard G. Badger, 1920.

Dr. Robie's work is to be criticized in order to commend his purpose, for one would bid godspeed to any such honest furtherance of sex knowledge. Yet one would wish that he went further back in order to go more forward. Robie has a genuine interest in his fellow men and women. It is an interest that cannot withhold itself from setting forth their needs plainly and helping them to adjust themselves in the way that health and happiness demand. He has done this and proved the sincerity of his position in his practice and is unafraid to promote his service still further in his writing. He has taken into account the ever present pressure of sex and followed it into the details of its manifestations. He has freed the knowledge of these from the misapprehensions and therefore the fear and shame which have too long surrounded them. In none of these things has he gone deeply enough into the fundamental psychological principles underlying all sex pressure as well as the difficulties in the way of its manifestations. Nor has he considered the details of psychical experience which adhere to the underlying psychology and complicate the difficulties, intensifying and resistances, fears, and the desires against which these are defenses. Robie does need that more labored consideration of psychoanalysis over which he is inclined to pass somewhat impatiently. We like his enthusiasm, his genuineness, yet his book would have gained rather than lost by more thorough digestion of facts. His rather exuberant style, hastily struck off diction, after all do not so thoroughly drive the truth home for acceptance as a more carefully chosen presentation might have done. At the same time one realizes the contagious interest with which he reaches his readers. Of course there must be different forms of presentation to reach differently thinking types of men and women.

The deeper criticism lies in the lack of the more

profound background of understanding. Robie pays so much attention, and not without right, to the sex need in itself that he gives the impression of exalting it and its forms of gratification somewhat out of relationship to the whole personality, to the responsibility to one's other interests and those of the herd. Not that we believe this is the practical effect upon himself or perhaps upon many of those he helps. But his book reads to that effect and one could be swung into such an attitude by the neglect of those other personal factors which have to be taken into account. In fact there would be probably those upon whom his broad advice could not work helpfully because these other factors are not sufficiently taken cognizance of. He has stressed the undeniable importance of the sexual segment in the makeup of a human individual. He has forgotten the struggles with its segment that this same personality makes, that is, has forgotten it in the light of this marked double pull in the personality.

Freud has called it the conflict of the sexual libido with the ego libido. Stekel has aphorized it as the conflict of brain and spinal cord. This brings in so many other possibilities for libido activity and the effort to withdraw sex libido to them or the opposition of other aims to sex libido that the problem is hardly so simple as Robie states it. It does involve those infantile elements, those earlier preliminary manifestations of sex and of sex struggle which he tends to disregard and rather indifferently to relegate to the Freudians. These also present such an aspect of things that some of his measures might be subject to question. To have a mother present sex problems so affectionately to her son as in the model letter quoted suggests the need of that caution which the study of child sexuality has taught us.

There are many problems of affection involved upon which Robie touches barely or not at all but without which sex cannot be fully grasped by the individual or one who would help him.

GERMAN SURGERY.

Chirurgie der Wirbelsäule, des Rückenmarks, der Bauchdecken und des Beckens. By Geh. Med.-Rat Prof. Dr. G. LEDDERHOSE, Munich, Germany. With a Foreword by Prof. Dr. J. SCHWALBE, Berlin. With Twenty Illustrations. Leipzig: Georg Thieme, 1921.

This little monograph of 160 pages covers in detail the surgery of the vertebral column, the spinal cord, abdominal walls and pelvis, with particular reference to diagnostic and therapeutic errors and their prevention. It is characterized by the usual German thoroughness and attention to detail. This may be illustrated by the discussion of the diseases of the navel, under which the following subjects are discussed: Inflammation and the formation of concretions; tumorlike indurations; adenomatous and primary carcinomatous formations; enteroteratoma; fistula; fistula of the vitelline duct; urinary fistula; cyst of the urachus; acquired fecal fistula; fistula of the navel secondary to liver and gallbladder diseases; fistula of peritoneal origin and recurring navel colic in children. The German reading surgeon who is willing to forget and forgive will find this little volume of considerable interest.

AMERICAN REVIEW OF TUBERCULOSIS.

The American Review of Tuberculosis. Journal of the National Tuberculosis Association. April and May, 1921. EDWARD R. BALDWIN, Saranac Lake, N. Y., Editor in Chief; ALLEN K. KRAUSE, Baltimore, Md., Managing Editor.

These numbers of the very popular and thoroughly scientific *American Review of Tuberculosis* are of unusual interest. The April number contains four of the most remarkable contributions which have been made of late on the various phases of the tuberculosis problem. The first is Sunlight and Artificial Light Therapy in Tuberculosis by Edgar Mayer. This is a historical and critical review of solar therapy, the physiology of light reaction and the action of light upon bacteria, the artificial sources of light, particularly the Finsen lamp and the Alpine quartz lamp and its various modifications; lastly, the therapeutic application of sunlight and its contraindications in pulmonary tuberculosis. The author also refers to the encouraging results of x ray and radium radiation in intestinal tuberculosis. In his conclusions he admits that insufficient comparative and statistical studies upon patients, especially upon those with pulmonary disease, leave much to be desired. Those interested in the subject of solar and artificial light therapy might care to look over the thirteen pages of bibliography on the subject which the author has added to his seventy pages of critical review of heliotherapy and artificial light therapy.

The next article is on the subject of Heliotherapy in Surgical Tuberculosis—Report of Results After Six and a Half Years Use at the J. N. Adam Memorial Hospital, by Clarence L. Hyde and Horace Lo Grasso, Perrysburg, N. Y. A mere glance at the twenty-six illustrations showing the cases before and after treatment is sufficient to arouse enthusiasm in any medical man over this new and yet so old remedy. The results obtained by Perrysburg seem to equal those obtained by Rollier of Leysin in Switzerland.

The two concluding articles in this number of the *American Review of Tuberculosis* are The Cost of Tuberculosis by Louis I. Dublin, the well known statistician of the Metropolitan Life Insurance Company, and Miss Jessamine Whitney, of the National Tuberculosis Association, and The Reason and Remedy for Missing the Early Tuberculous Lesion by Henry F. Stoll. Both articles deserve a careful perusal by all students interested in the social and clinical aspects of tuberculosis.

The May number is also of unusual interest. It contains the following contributions: Studies on Tuberculous Infection—VIII, Spontaneous Pneumoconiosis in the Guinea pig, by Henry Stuart Willis; The Focal Reaction, by William F. Petersen; The Importance of Subliminal Symptoms and Period of Alternation of Rest and Exercise in the Treatment of Pulmonary Tuberculosis, by Henry Sewall; Additional Diagnostic Methods for Cases of Suspected Intraocular Tuberculosis, by A. H. W. Caulfield; The Adrenals and Thyroid in Experimental Tuberculosis, by G. B. Webb, G. B. Gilbert and C. T. Ryder.

Dr. Willis's contribution has a preface by Allen K. Krause in which he justly says that the advan-

tages of such a study are plain and it is to be hoped that it may throw light upon some features of experimental anthracosis which have remained obscure because of technical obstacles. The titles of the four other articles and their well known authors speak for their importance, but to review them even in part would take more space than can be given to reviewing in a medical journal. However, attention should be called to the fact that the May number of the *American Review of Tuberculosis* has over ten pages of valuable abstracts from the most important articles on tuberculosis which have appeared recently in European and American medical magazines.

New Publications Received.

◆

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

RESURRECTING LIFE. By MICHAEL STRANGE. With Drawings by JOHN BARRYMORE. New York: Alfred A. Knopf, 1921. Pp. 86.

OUTWITTING OUR NERVES. A Primer of Psychotherapy. By JOSEPHINE A. JACKSON, M. D., and HELEN M. SALISBURY. New York: The Century Company, 1921. Pp. 403.

THE RUSSIAN BOLSHEVIK REVOLUTION. By EDWARD OESWORTH ROSS, Ph. D., LL. D., Professor of Sociology, University of Wisconsin. Illustrated with Over Thirty Photographs. New York: The Century Company, 1921. Pp. xvi-302.

CZECHOSLOVAK STORIES. The Interpreters' Series. Translated from the Original and Edited with an Introduction by Sarka B. Hrbkova, Professor of Slavonic Languages and Literatures at the University of Nebraska (1908-1919). New York: Duffield & Company, 1920. Pp. iv-330.

HUMAN BEHAVIOR. In Relation to the Study of Educational, Social and Ethical Problems. By Stewart Paton, M. D., Ex-President, Eugenics Research Association; Lecturer in Neuro-Biology, Princeton University; Author of *Textbook on Psychiatry and Education in War and Peace*. New York: Charles Scribner's Sons, 1921. Pp. 465.

THE DIAGNOSIS AND TREATMENT OF INTUSSUSCEPTION. By CHARLES P. B. CLUBBE, L. R. C. P., M. R. C. S., Consulting Surgeon to the Royal Prince Alfred Hospital; Consulting Surgeon to the Coast Hospital, Sydney; Honorable Surgeon to the Royal Alexandra Hospital for Children; Late Lecturer in Clinical Surgery, University of Sydney, New South Wales. Second Edition. London: Henry Frowde, Hodder & Stoughton, 1921. Pp. x-91.

TRAUMATIC SURGERY. By JOHN J. MOORHEAD, B. S., M. D., F. A. C. S. Late Lt.-Colonel, Medical Corps, American Expeditionary Forces; Professor of Surgery and Director, Department of Traumatic Surgery, New York Post-Graduate Medical School and Hospital; Visiting Surgeon to Harlem Hospital; Attending Surgeon, Park Hospital; Consulting Surgeon, All Souls' Hospital (Morristown, N. J.); Lt.-Colonel, Medical Reserve Corps, U. S. Army. Second Edition Entirely Reset. Philadelphia and London: W. B. Saunders Co., 1921. Pp. 864.

MANSON'S TROPICAL DISEASES, A MANUAL OF THE DISEASES OF WARM CLIMATES. Edited by Philip H. Manson-Bahr, D. S. O., M. A., M. D. (D. T. M. and H.) Cantab. M. R. C. P. Lond. Physician to the Hospital for Tropical Diseases, London, and the Albert Dock Hospital; Lecturer at the London School of Tropical Medicine; Lecturer on Tropical Diseases at the North-East London Post-Graduate College; Examiner in Tropical Medicine to Cambridge University. Seventh Edition, Revised and Enlarged. With Twenty-one Color Plates, Six Half-tone Plates, 404 Figures in the Text, and Thirty-one Charts. New York: William Wood & Company, 1921. Pp. xvi-960.

Practical Therapeutics

MARIENBAD SPRINGS

BY ERNEST F. KERBY, M. D.,
New York.

Ancient chronicles dating back to the fourteenth century contain references to the therapeutic properties of natural mineral springs. Paracelsus, in the sixteenth century, extolled their virtues and sought a scientific explanation of their mode of action. More than a hundred years ago Marienbad was already established as a health resort of great renown on account of the potency and variety of the natural springs with which nature has blessed this pretty Bohemian town. To be able to realize fully the wide appeal of the Marienbad cure one has to visit the city at the height of the season, when inhabitants of every conceivable country flock together on their annual pilgrimage in search of health. It is in keeping with the spirit of our times that the Marienbad municipality has decided to annihilate distance by exporting their products into remote countries, so that the natural treasures are accessible to all instead of being reserved for the few who can undertake the voyage to the springs. The news that Marienbad products will be available for general use in this country, will be hailed with satisfaction by all physicians who have had an opportunity in the past to become acquainted with their therapeutic possibilities. It appears opportune at this juncture to give a description of the outstanding features of the principal springs and to discuss their mode of action.

Kreuzbrunnen is one of the most important of the Marienbad springs. Its chief constituents are sodium sulphate and sodium bicarbonate and it also contains appreciable quantities of calcium and magnesium bicarbonates. The essential action of this water consists, therefore, in promoting increased elimination. It is of interest to point out in this connection that the usual explanation of the action of saline cathartics has become untenable in the light of recent pharmacological researches. For long the theory had been accepted that all members of this group of purgatives derived their potency from the fact that they are not absorbed by the intestinal mucosa and that for this reason a large amount of water is retained within the lumen of the gut in accordance with osmotic requirements. The resulting increase in bulk of intestinal contents was then thought to incite more vigorous peristalsis. The simple observation that a full dose of salts usually calls forth a watery evacuation shortly after it has entered the stomach, served to indicate that the problem was more complicated. It has been definitely established (1) by accurate observations in cases of ileal fistulae and by means of x ray examinations that the salts administered only reached the cecum four hours after ingestion in cases where a copious evacuation had resulted after two to three hours. It must, therefore, be concluded that absorption had actually taken place in the small intestine, and that the salts in circulation had stimu-

lated the nervous mechanism of the colon. An important finding is the fact that up to fifty per cent. of the sodium sulphate administered is excreted by the kidneys within eight hours. Clearly, therefore, the action of the saline group is more complex than has been generally assumed.

These observations give a clue to the properties of Kreuzbrunnen which is probably used more extensively than any other Marienbad spring. It increases elimination without irritating the intestinal mucosa or renal epithelium. Experience has shown that it is suitable for prolonged courses of administration without deleterious effects. It has, therefore, a wide range of utility in chronic intestinal catarrhs and habitual constipation. As the stools are rendered soft and unirritating, Kreuzbrunnen is gratefully appreciated by sufferers from hemorrhoids, anal ulceration, and painful pelvic conditions. The typical Marienbad cure has as its aim the reduction of excessive adiposity. This is a problem which is receiving increasingly vivid attention, since the interpretation of life insurance statistics has demonstrated its true significance from the point of view of preventive medicine. It has been shown that the expectation of life decreases proportionally as the weight rises above the normal average. The unhygienic habits of life which economic necessity is forcing upon the majority of people at the present time, all tend to swell the ranks of the overweights.

Small wonder, therefore, that Kreuzbrunnen, the time honored specific against obesity, is enjoying increasing popularity. It is also used for a variety of disorders of allied etiology, such as arteriosclerosis, elevated blood pressure, fatty degeneration of the heart, and for congestive conditions generally. Finally, patients suffering from renal insufficiency often experience striking relief during a course of Kreuzbrunnen; owing to the increase of elimination effected, many of their symptoms are alleviated and their sense of well being and their capacity for useful occupation are increased.

The details of a course of treatment vary naturally with the individual needs of the patient. On the whole, the chief aim has been to obtain the largest possible daily stool. A different plan of treatment has been advocated by Rheinboldt (2). He suggests a subdivision of the course into three periods. During the first, the dose of the water is varied, until the minimum amount is determined, which will insure one normal stool every morning. Throughout the second period the patient establishes the habit of obtaining, with the help of the minimum dose, a full daily evacuation. When this aim has been fully attained, the last period is entered upon; during that time the dose is gradually diminished by substituting a weaker water and, finally, plain water. This course of treatment occupies at least four weeks. It goes without saying that the general hygienic régime of the patient receives due attention at the same time.

The outstanding characteristic of the Rudolfsquelle is its richness in calcium and magnesium bicarbonates. It also contains protoxide of iron. This water is used chiefly on account of its alkaline properties, and it may be taken for long periods without interruption. It is prescribed for patients suffering from gouty manifestations and renal calculi. Reliable results may be expected in cases, where the urine is unduly acid or where it is to be rendered alkaline in inflammatory conditions of the kidney, bladder, and genitourinary passages. Rudolfsquelle has been used tentatively in a number of disorders thought to be dependent on, or accompanied by diminution of the alkali reserves of the blood. This miscellaneous list includes affections like diabetes, chronic eczema, and liability to attacks of bronchitis and frequent catarrhs of the upper respiratory tract. Another field of utility is represented by the group of disturbances associated with hyperacidity of the gastric secretion. The combined administration of Kreuzbrunnēn and Rudolfsquelle offers some practical advantages in the treatment of gastritis and gastric and duodenal ulcers, as well as after gastrojejunostomy. Hyperemesis gravidarum, especially if accompanied by acidosis, may also be included in this group from a therapeutic point of view. In all these conditions the two Marienbad waters solve the problem of neutralization of acid and of increasing elimination in a convenient and pleasant fashion.

By a process of evaporation of Kreuzbrunnēn and Ferdinandsquelle Marienbad spring salt is prepared. It has been widely employed in the place of the waters, especially where a reduction of the bulk was desired for greater convenience.

Our knowledge of the ultimate properties of natural springs, especially as compared with artificial solutions, is still rather incomplete. Of course it must be realized that the results of analysis of the various spring waters only reflect the temporary state of our knowledge of chemistry. Thus, with the growth of this science, the analytical tables have undergone repeated changes. One of the latest additions, for instance, is the discovery of helium in the springs. This may or may not be of therapeutic importance, but it serves to show that our knowledge even of the chemical composition of Marienbad waters cannot be considered to be complete. This applies with still greater force to the physicochemical problems involved. We have only recently learned to attach importance to colloidal phenomena and the varying rates of ionic dissociation of salts in solution. Further research along these lines may assist in throwing some light on the difference between natural and artificial solutions. Another chapter of inquiry was opened soon after Madam Curie's discovery of radium, when it was shown that Marienbad springs were endowed with a remarkably high degree of radioactivity. This is due to the presence of radioactive ore deposits in the geological formation of the district Marienbad is situated in. Joachimsthal, the famous centre of radium production, belongs to the same region. The suggestion that radioactivity of the springs may enhance their curative effects appeared for a long time to be not a solution of the problem, but merely

a restatement of it under another guise. However, recent researches have brought some explanations. It is now definitely established that, while strong doses of radium destroy, small doses on the contrary stimulate the physiological activity of cells (3). This property has been made use of in actinotherapy with unequivocal results. For instance, exposure of the spleen and of the bone marrow gives rise to an increase in the production of erythrocytes. The same principle has been applied in the treatment of organs, the function of which is deficient owing to pathological changes. Thus the amount of urine excreted has been markedly increased in cases of renal insufficiency due to chronic nephritis. The next link in the chain of evidence was the demonstration of the fact that the presence of radioactive substances in the blood stream exerted a stimulating effect on the tissues of a nature identical to that obtained by direct radiation. It is, therefore, conceivable that the secret of the efficiency of Marienbad waters—the mysterious "spirit of the spring" hinted at by ancient writers—depends on radioactive properties and special physicochemical factors as much as on the felicitous combination of its mineral salts.

Renal Function in Vascular Hypertension.—James P. O'Hare (*Boston Medical and Surgical Journal*, April 1, 1920) considers it very important to differentiate vascular hypertension from chronic nephritis. While both may show albumin and casts, the lesion in the kidney of the vascular hypertension case is very slight and confined chiefly to the vessels, while in the chronic nephritic the process is largely in the renal parenchyma. The latter lesion is usually progressive, whereas in the former the disease in the renal vessels is stationary or so slow that its progress can scarcely be recognized. The great majority of patients with vascular hypertension die from cerebral hemorrhage, some from cardiac disease, but in only a few does the disease of the renal vessels become so great that the parenchyma is progressively reduced and uremia supervenes. The treatment of vascular hypertension has often been unnecessarily rigorous because of the mistaken diagnosis. The vascular hypertension patient can be recognized clinically by his characteristic healthy appearance, his lack of pure renal symptoms, and by routine physical and laboratory examination, especially by the tests of renal function. Twenty-five cases of vascular hypertension are tabulated to show how readily the functional tests in common use establish the diagnosis. It is briefly summarized by saying that in vascular hypertension: 1. The specific gravity of the urine shows no loss of power of concentration, as in chronic nephritis; 2, albumin and casts appear in the same quantities in both diseases; 3, the functional tests show but little renal impairment; 4, a markedly increased night volume of urine indicates a possible renal death.

Treatment of the Chronic Intestinal Invalid.—

John Bryant (*American Journal of the Medical Sciences*, January, 1921) says that there are five distinct factors of fundamental importance in treatment of the chronic intestinal invalid, which are social, mental, dietary, orthopedic, and glandular. The common objective of all these factors is increased resistance of the patient to fatigue, and they must be applied in overlapping sequence in order to yield the maximum benefit. The chronic intestinal invalid usually recovers at a rate inversely proportionate to the amount of surgery to which he has been subjected. The physician who will take the time and trouble may promise such a patient a ninety per cent. prospect of a reasonable degree of improvement, and an eighty per cent. prospect of a marked or satisfactory degree of improvement as a result of a few months of nonsurgical treatment. Treatment which does not train the patient to avoid or to recover from future relapses with a minimum of medical assistance, falls short of what the chronic intestinal invalid has a right to expect.

Pathological Changes in the Striped Muscles in Choleric Diarrhea.—H. Sloboziano (*Presse médicale*, January 12, 1921), in three out of six cases of cholera infantum, found acute fatty degeneration of the myocardial cells, which accounted for the small pulse and bradycardia witnessed in these cases during life. The other striped muscles, including the diaphragm, rectus abdominis and psoas, examined in eight patients, were found involved eight times out of a total of thirteen muscles studied. They showed either acute disseminated degeneration, cloudy swelling, or fibrillar aspect of the muscle cells. The dyspnea of cholera infantum may be partly attributed to changes in the myocardium and muscles of respiration. The poison of the disease is apparently soluble in the fatty substances normally present in certain amount in the muscles of small children, and its dissolution in them promotes injury of the cells. After the second year of life these cellular fats are present only in much smaller amount, and choleric diarrhea therefore to a marked degree loses its serious aspect in such children.

The Relation of Fistula in Ano to Phthisis.—Herman A. Brav (*American Medicine*, December, 1920), from personal observation, is led to the following conclusions:

1. Tuberculous fistula of the anus is usually secondary to tuberculous disease of the lungs.
2. Pulmonary phthisis is rarely, if ever, secondary to fistula in ano, either before or after operation.
3. Tuberculosis of the anal region should be dealt with radically, as wounds upon the consumptive heal more readily than is generally supposed.
4. When the patient's general condition will permit, the surgeon should operate on all fistulas, regardless of their type.
5. The surgeon should not refuse to operate on persons suffering from a mild form of phthisis, for in incipient cases the operation is always justifiable.
6. There is no reason why a tuberculous focus should not be extirpated here as elsewhere. The operation should be followed by a scraping of the fistulous tract. Unless the lung trouble is active and far advanced, operation is not contraindicated.

Streptococcal Leptomeningitis Due to Chronic Suppurative Otitis Media.—S. Scott (*Lancet*, November 27, 1920) discussed the case of a ten year old girl who had ear discharge some months before. Symptoms were headache, vomiting, sensation of falling, and twitching of face and arms, followed by coma, retraction of the head, and extensor rigidity of the hamstrings. Her temperature was 104°, pulse 130, and respiration 30. The radical mastoid operation, with translabyrinthine drainage and lumbar thecal, was performed. The mastoid antrum and cells contained pus, granular and cholesteatomatous material. An extradural abscess contained nearly a dram of pus. The wound was packed open with dressings. Lumbar puncture, repeated every twelve hours, on the fourth day revealed sterile spinal fluid. On the fifth day, the child was convalescing.

Primary Disease of the Pelvic Lymph Glands.

—John T. Williams (*Boston Medical and Surgical Journal*, February 24, 1921) asserts that primary enlargement of the pelvic lymph glands is a distinct clinical entity. The diagnosis is to be based upon a pelvic mass definitely not connected with the uterus or its appendages, which gives rise to pain and tenderness in the iliac fossa of the affected side, with or without elevation of temperature, and with or without psoas spasm on the affected side. The white count in the few cases so far observed has been only slightly increased. The treatment is the same as that of enlarged or diseased glands elsewhere in the body. A mass definitely containing pus should be opened. Where the glands are acutely inflamed but suppuration has not taken place, treatment should be restricted to rest and cold applications. Where the enlargement causes pressure on important organs and does not rapidly subside under palliative treatment, excision is indicated.

The Peristalticlike Nature of Organic Responses.—P. F. Swindle (*American Journal of Psychology*, April, 1919) concludes that reasons were given for supposing that all muscular responses of long duration are discontinuous in the sense that the nervous correlates of a limited portion of such a response are not exactly identical with those of any other portion of the same response. Assuming, then, the discontinuity of all the muscular responses or the peristalticlike nature of responses in general, and speaking only of the behavior correlates of the structures that function, the following law of induction can be stated: The initial element of the innately associated series of elements of the responses of long duration conditions or induces its qualitatively most similar element; this in turn induces its most similar element which has not occurred immediately before, and so on until the qualitatively most dissimilar element to the initial one is induced. This law is essentially the same as a law of color induction, stated as follows: In successive and simultaneous color induction, any color induces first itself and last of all its antagonistic color. The only difference between the two statements of the same law of behavior is that, in the one case, emphasis is laid upon the qualitative natures of the muscular movements which succeed one another, while in the other the succession of psychical states only are brought into consideration.

Acute Lobar Pneumonia; Treatment.—A. L. Burnett (*Colorado Medicine*, January, 1921) sums up the treatment of this disease in these four rules: 1. Afford good hygiene and careful nursing. 2. Conserve and replenish the patient's energy. 3. Promote active elimination. 4. Treat the symptoms when they arise, not before.

Raised Blood Pressure.—Paul M. Chapman (*Practitioner*, January, 1921) says that we must not assume all high blood pressures to be evil, and suggests that the following considerations are worth remembering: 1. The nourishment of the cardiac muscle is conditioned by the blood pressure in the aorta. 2. A plus pressure often means increased cardiac vigor. 3. A minus pressure often entails cardiac malnutrition. 4. A plus pressure should not always, as a matter of routine, be taken to be harmful. 5. The condition of the patient himself under treatment is as yet all we have to go by, and we have to consider every circumstance before we can exercise a proper discretion in our treatment of blood pressure, except in extreme cases.

The Orbital Cardiac Murmur.—A. E. Vipond (*American Medicine*, March, 1921) reports nine cases where a systolic murmur was heard over the orbit. He has found it in Graves's disease, endocarditis, aortic and mitral valvular disease, in dextrocardia and in congenital heart disease. To detect this orbital murmur the room should be free from noise and the murmur is exaggerated by making the patient exercise before examination. The stethoscope used was the ordinary Bowles type, placed over the eyeball, with the eyelids closed, a little to the outer side to exclude respiratory nasal sounds. This murmur was never found in connection with the normal heart.

Letters to the Editors.

MAN VERSUS THE MICROBE.

To the Editors:

NEW YORK, May 21, 1921.

It is always a pleasure to the old chap to see a return to sane thinking. This is true in the world at large; it is also true, but in a greater degree, in what relates to medicine, when one is or has been during many years an all around practitioner. No one believes more than I do in the proven specificity of some microbes in the causation of disease, or indeed, when present, in their farreaching importance in some local injuries. But, when at every turn in the road, everywhere and among all people, there is the continuous outcry against the ever-present and inimical microbe and what terrible consequences arise from its presence, unless it is neutralized, its poison made nonexistent, and this, too, by powerful, so-called disinfectants, then the thoughtful mind cries a revolt.

To me, the effort made in so many directions and the expense in mind, body and estate, to bring to an end, or greatly diminish the great white plague (tuberculosis) are sadly lacking in sanity. If tuberculosis were very contagious to the larger number of men, women and children, where would we be with our abominable housing and methods of traffic

in which fellow humans are crowded like cattle for not a short time of the twenty-four hours. It is only contagious, as I believe, in very small measure and only then when the soil is ripe for its culture. Let us stop this outcry for more sanitariums and too much regulated lives for the very few, relatively.

Let us return, or rather advance more and more to the sane judgment that good surroundings—healthful, sufficient air space, with sunlight and sufficient nutritious food, properly prepared, are the essentials in our combat against this disease and indeed, against many others of supposed infectious or contagious type, or which in some instances are proved to be so.

In some of these cases, like influenza, they are air borne, as I believe,—but the microbe itself has small importance. What the real poison of the disease is we do not know and may not know for a long time in the future. While we do know that a few diseases, but again, relatively few, are connected primarily, always up to date, with the presence of a microbe, singly or combined, its power for evil is not always the same. Sometimes it is very virulent, but the cases are in main few. Again, the microbe, the *habitat* of the poison, carries with it slight danger to the one attacked, but is very widely disseminated. I have merely to mention what occurs in epidemics of scarlet fever, of measles, of whooping cough, to carry home the truth of my statements.

The sooner we learn and bring to mind constantly that microbes are often so-called scavengers of disease, and not the initial, most important cause, the better for the world and now, the too much and unnecessarily frightened humanity. Let our main watchwords be: more and better homes, sufficient good, nutritious food, sunlight, sanitary employments, and also, in time of sickness, a few well selected and useful drugs, or combinations, from the old doctor's storehouse of wide observation and experience, backed up with a great fund of intelligence, integrity and common sense.

BEVERLEY ROBINSON, M. D.

129 EAST THIRTY-FIFTH STREET,

TOBACCO.

WILKES-BARRE, PA., June 15, 1921.

To the Editors:

In article, "The Effect of Tobacco on Man," by Gies, Kahn and Limerick, page 810, the following paragraph will be found:

The sequence of the potency of the different forms in which tobacco is generally used runs as follows, in the order of greatest degree to least: Chewing, smoking pipe, smoking cigar, smoking cigarette. It can thus be seen that, contrary to the prevailing belief among laymen, the cigarette is in fact the least harmful form in which it is possible to habitually use tobacco. There is not the slightest foundation for the popular notion that the paper or the tobacco used in the manufacture of the cigarette contains any substance that is especially injurious to the human organism. Emphasis on the relative innocuousness of the cigarette is deemed justified by the persistence with which the misinformed strive to convey a contrary impression. It is equally deserving of mention that analysis of tobacco does not indicate with any degree of preciseness the actual toxicity of, say, a cigar or a cigarette made of it, for a great part of the volatile constituents of the plant is completely destroyed in the burning, hence does not enter the body.

With this paragraph I wish to take exceptions. At my request, Mr. Joseph J. Walsh (Inspector of Mines), of Nanticoke, Pa., made tests. The following is his report:

For the purpose of determining the amount of carbon monoxide in the gases drawn through a cigarette, and also to determine what amount of carbon monoxide is absorbed by the tissues of the mouth, samples of the products due to this form of combustion was collected in the following manner: A rubber bulb force pump was used for the purpose of collecting the samples. The pump consists of a rubber bulb and two short rubber tubes, one attached to each side of the bulb, the whole being fitted with a valve mechanism. When the bulb is compressed its contents are forced through the discharge tube, and, when released, it expands, drawing air in by other tube, which forms an inlet. Sample number one was collected by putting the discharge tube into a sample bottle and inserting a lighted cigarette in the intake tube; the bulb was then pressed and inflated fifteen times, thus pumping into the sample bottle a sample of the products of combustion. Sample number two was collected by means of same instrument and in the same manner, excepting that the discharge tube was placed in the mouth, into which a sample of the products of combustion was pumped, which sample then passed from the mouth through a glass tube into a sample bottle.

SAMPLE NUMBER ONE.

Carbon dioxide	2.09 per cent.
Carbon monoxide	2.22 per cent.
Oxygen	16.23 per cent.

SAMPLE NUMBER TWO.

Carbon dioxide	3.00 per cent.
Carbon monoxide	1.63 per cent.
Oxygen	15.40 per cent.

The following samples were drawn through a lighted smoking pipe, and collected in the same manner as above. Sample three was pumped directly into the bottle; sample number four passed through the mouth:

SAMPLE NUMBER THREE.

Carbon dioxide	4.10 per cent.
Carbon monoxide	2.75 per cent.
Oxygen	14.00 per cent.

SAMPLE NUMBER FOUR.

Carbon dioxide	4.46 per cent.
Carbon monoxide	2.08 per cent.
Oxygen	14.30 per cent.

The following is the result of analysis of air expelled from the lungs while in the ordinary performance of work:

AIR EXPELLED FROM THE LUNGS.

Carbon dioxide	3.67 per cent.
Oxygen	17.22 per cent.
Nitrogen	79.11 per cent.
Carbon monoxide	0.00

PURE AIR.

Carbon dioxide03 per cent.
Oxygen	20.93 per cent.
Nitrogen	79.04 per cent.

From these analyses it is apparent that from six to seven tenths of one per cent. of the carbon monoxide contained in the gases given off during smoking are absorbed in the upper air passages. Inhaling the smoke would materially increase the amount of carbon monoxide absorption, and the continued absorption of carbon monoxide certainly

would have a deleterious effect on the human organism.

The continuous inhalation of one fifth of one per cent. of carbon monoxide for a period of six hours is sufficient to cause death. As the cigarette smoker is, as a rule, an inhaler, I cannot understand why assertion is made that the cigarette is the least harmful form of tobacco, especially when the smoker absorbs a larger amount of carbon monoxide.

27 EAST SOUTH STREET. D. W. COLLINS, M. D.

TOBACCO.

To the Editors:

NEW YORK, June 17, 1921.

"The cigarette is, in fact, the least harmful form in which it is possible habitually to use tobacco," because it yields the smallest amount of toxic materials.

As far as they extend, the tests reported to have been made by Mr. Joseph J. Walsh and quoted by Dr. D. W. Collins confirm what has been said by my collaborators and me of the relative innocuousness of the cigarette.

Carbon monoxide is not the most toxic constituent of tobacco smoke. The inhalation of tobacco smoke is not confined to cigarette smokers.

Persons habituated to the cigarette usually exhibit the more profound symptoms of acute tobaccoism after having smoked a cigar or a pipe, which fact proves the greater potency of the latter forms of smoking tobacco.

550 RIVERSIDE DRIVE. O. VICTOR LIMERICK.

CONTAGION.

To the Editors:

NEW YORK, May 23, 1921.

In your issue of May 18, 1921, page 751, Dr. Arthur I. Blau, signing himself as diagnostician, Department of Health, writes as follows:

Not infrequently I encounter cases of contagion in premises, the seat of that contagion weeks or months ago. This occurrence, in my mind, is not merely incidental. It is a late infection caused by the germ or poison of contagion still present in those premises, left over by the patient after recovery, which has not been removed or destroyed by the disinfection or renovation. This is not a mere assumption, for we know that the poison of the contagious diseases is very tenacious, particularly that of scarlet fever, and clings for weeks or months to furniture, carpets, and other household articles.

Inasmuch as these views were submitted for publication without my knowledge and are directly at variance with the teaching and practice of the New York City Department of Health, I request that you publish this letter in order that the readers of the JOURNAL may not be misled.

After prolonged and thorough experimentation, both in the field and the laboratory, the department decided that terminal disinfection was wholly ineffective in diminishing the spread of contagion. The department believes that persons, either as patients, convalescents or carriers, are practically the sole source of infection. Together with thorough concurrent disinfection, the department finds that procedures based on the above belief are entirely satisfactory.

LOUIS J. HARRIS, Director,
BUREAU OF PREVENTABLE DISEASES.

Collectanea

The Status of Vaccination Against Influenza.

—Prophylactic vaccination against influenza was practised extensively during, but mostly following, the recent epidemic of the disease. From a scientific point of view, such inoculation seems somewhat premature, since the etiological factors are not established, says the *Journal A. M. A.*, May 28, 1921. In some districts stock cultures were employed; in others a culture of a strain or strains isolated during the epidemic, and in still others a mixed vaccine composed of the bacillus of Pfeiffer, the streptococcus, the pneumococcus, the staphylococcus and other organisms. McCoy presented his impression, as gained from the uncontrolled use of these vaccines, that while theoretically they might be of value in the prevention of influenza, yet in every case in which they were tried under perfectly controlled conditions they failed to influence either morbidity or mortality. A well conducted investigation is worthy of note even when the outcome is negative in character. It may turn us away from false hopes and force us to seek new solutions for the problem at hand. In an elaborate study, Jordan and Sharp of the Department of Hygiene at the University of Chicago conducted observations under the auspices of the influenza commission established by the Metropolitan Life Insurance Company of New York on approximately six thousand persons from November, 1919, to June, 1920. About one half of these were vaccinated with a saline suspension of a standard mixed vaccine prepared by Dr. W. H. Park, of the New York City health department. The remaining half were not vaccinated. Comparable members of the two groups in different localities lived under essentially identical environmental conditions. The influenza attacks among the vaccinated numbered 118, or 4.1

per cent.; among the unvaccinated the morbidity from this disease was 4.8 per cent. Rhinitis and bronchitis developed with about equal frequency in the two groups. There were slight variations in the incidence of the few cases of pneumonia, but the Chicago bacteriologists regard it as unlikely that any considerable degree of protection against influenza was conferred. Is it unfair to the proponents of vaccination against influenza and other respiratory infections to say: "Value unproven"?

The Psychopathology of the Fugue.—Erwin Popper (*Monatschrift für Psychiatrie und Neurologie*, March, 1920) describes the case of a student who left his school and was found some days later on the school grounds suffering from a total amnesia extending over a week's time. Letters describing his travels were subsequently received. The student had always appeared normal, although he indulged in phantasy stories and descriptions of his exploits and travels. He himself denied all knowledge of these phantasies. The fugue is interpreted as a type of hysterical wish fulfilment delirium. His fantasy life together with his normal life constitute an hysterical double personality. It is particularly striking that the retrograde amnesia extends over all the periods of apparent pseudologia phantastica, in this way appearing as an hysterical repression of all these periods. No further analysis of the patient to overcome the hysteria was attempted.

High Mortality Rates.—In the United States in 1919 one mother died for every 135 babies born, and every eleventh baby born died before he was a year old. That these rates are excessive is shown in a bulletin issued by the United States Department of Labor through the Children's Bureau, and just revised to compare the latest rates for the United States with those for foreign countries.

Six countries are shown to have a lower infant mortality, and sixteen in a group of seventeen a lower maternal mortality than the United States. Not only do we lose more mothers in proportion to births than practically any other civilized country, but we apparently lose more on an average each year than the year before. Whereas in other countries there has been a decrease in the death rate from childbirth, the rate in the United States arose from 6.1 in one thousand births in 1915 to 6.2 in 1916, 6.6 in 1917 and to 7.4 in 1919. Moreover, in this country there is no appreciable decrease in the proportion of babies who die from causes largely connected with the care and condition of the mother.

Experience has proved, the bulletin points out, that thousands of deaths of both mothers and children could be prevented every year by public measures for the protection of maternity and infancy. In New York city, among 4,496 mothers who were supervised by the New York Maternity Centre Association before and after the birth of their babies, the maternal mortality rate was less than one third the rate of the United States and the rate for deaths in early infancy was less than half that for the city as a whole. In other cities of the United States and in foreign countries the institution of infant welfare measures has been followed by greatly decreased rates.

Some Remarks on the Elements of Diet in Infancy, with Special Reference to the Employment of Czerny and Kleinschmidt's Butter Flour Mixture*

By J. P. CROZER GRIFFITH, M. D.,
Philadelphia,
and
A. GRAEME MITCHELL, M. D.,
Philadelphia.

In an article by Czerny and Kleinschmidt (1) describing the method of production and the results of the employment of their butter flour mixture, they open with the explanation of the thought which led to the construction of the product. They speak of the composition of human milk and the consequent suggestion which presents itself—that there is probably something in Nature which demands for the infant the relative proportions of fat, protein, and carbohydrate which exist in the milk the human breast supplies. They speak, too, of the assumption by many that it is a matter of indifference whether the fat of the food is largely or entirely replaced by carbohydrate; and evidently do not believe that this is correct, leaving it for the writers who make this assertion to bring forward positive proof in support of it.

These statements, emanating as they do from writers of such well known distinction, and opposing, as they do, so many expressed views of other investigators likewise of prominence, naturally arouse interest and stimulate the desire to know just what is to be considered most nearly correct in this much discussed question. It is evident that it is a question as yet far from final solution; yet the thought has long been present with us that the giving of high protein percentages to normal infants was not a matter of indifference, and that even the use of such food in many cases of digestive disturbance might be harmful rather than beneficial. Further, it has always seemed to us a question whether the substitution of fat by large percentages of carbohydrate, useful as it is in so many cases, was one which was to be persisted with as entirely satisfactory after health had been regained. Our conviction has long been that a relationship in diet closer in some respects to the proportions seen in

human milk was eminently desirable. These views are, of course, shared by many others, and have been repeatedly expressed by them; and yet much that one reads in modern medical literature would lead to the idea that they were without satisfactory scientific foundation. Many writers in their attempt to simplify infant feeding have gone to such an extreme that the efforts would seem to be toward rendering the preparation easy for the physician rather than to make the food the most suitable for the infant; and we see methods and formulæ recommended which are a reversion to those which the experience of many years ago had relegated to the undesirable.

A review of the enormous literature on the subject of the digestion and action of the different ingredients of the infant's diet is, of course, out of the question; but reference to a few of the more important comparatively recent statements in medical literature in support of our contention may well be permitted.

As regards the protein, Benjamin (2) in a long article of over one hundred pages gives an exhaustive review of the literature of the subject, and details his own experiments. He speaks of the undoubted injuries which may follow the employment of an excess of protein, noted especially in a continued failure to gain weight and a general muscular atony, such as is often seen in the employment of protein milk. The fact that malt soup is often a remedy for this condition has been attributed to its low fat and high carbohydrate percentage; but it must not be forgotten that it also possesses a percentage of protein which is low, and he believes that the essential factor in many instances. Glanzmann (3) studied the effect of casein milk in various diseases, and found that when it was given in over-amount, evidences of injury from protein developed, shown by unhealthy appearance, pallor, loss of strength, meteorism, and subfebrile temperature.

*From the Wards of the Children's Hospital of Philadelphia and the Children's Medical Ward of the Hospital of the University of Pennsylvania.

He regards it, therefore, as an unsuitable diet for a healthy child, and not adapted for long employment even in those with digestive disorders. Hoobler (4) in a careful study of the subject details his own experiments, which confirm the views of others that protein is often given too freely. Whereas seven per cent. of the total calories represents the utmost need of the infant, in such foods as that recommended by Finkelstein the protein is about thirty per cent. Protein fed in excess causes an increase of the protein metabolism, but does not reduce the amount of the fat and carbohydrate metabolized, which must then be drawn from the stored up fat and glycogen, unless sufficient is supplied in the food. When fed greatly beyond its need protein is likely to produce a condition of stupor. He thinks the employment of any high protein diet is justified only as a temporary therapeutic measure. Howland and Stolte (5) found that the addition of casein to the diet of breastfed children did, it is true, increase the weight, but caused the development of exudative symptoms and diminished decidedly the calcium balance. A very useful review of the literature of the subject, together with his own experiences, is given by Tanaka (6). It would appear from this that although infants absorb an excess of protein readily, they are unable to retain it, indicating that there has been an overburdening of the system by protein. The children to whom a high protein diet was administered finally entirely ceased to gain. Finally Bessau (7) in a long article upon the pathology of injuries by milk maintains that there is no more doubt about the production of injury by the action of the protein than there is by that of the fat, and by this he does not mean merely evidences of indigestion. The protein can produce damage not only through a lack of perfect proportion among the milk elements, but by the presence of an actual quantitative excess, and he asserts that the well known blue gray coloration of the skin often seen in infants fed on casein milk is a symptom of the high protein diet.

The references given are selected from many, and are enough, we believe, to show that both clinical experience and metabolic investigations support the opinion that a high protein diet, except for certain specific purposes, is not desirable, and that the difference in the ratios of fat and protein as seen in human milk and in cow's milk, respectively, is of significance.

As regards the fat and the carbohydrate of the food, the injuries which may follow a high percentage of fat are too well known to demand any discussion. The cause of this is not so certain. The relief of vomiting by the butter flour mixture, to which we shall refer later, appears to lend proof to the opinion that the difficulty in the digestion of cow's milk fat depends upon the high percentage of volatile fatty acids present. The favorable experience, however, of Moro (8) and of Rietschel (9) with foods analogous in composition to the Czerny-Kleinschmidt butter flour mixture, yet prepared without any driving off of the fatty acids by cooking, would indicate that there may be other reasons for the fact that the high fat percentage in this mixture does not increase the tendency to vomit. Many

cases suggest that a common cause of injury by fat is through the formation of soap stools, while diarrhea produced by an excess of fat occasions a loss of the alkalies and a diminished calcium absorption (Holt, Courtney, and Fales) (10). On the other hand, the importance of fat in the diet is a matter which cannot be disputed. Holt, Courtney, and Fales assert that a certain percentage of fat must be present to obtain a satisfactory absorption of calcium, and recent testimony from other writers is all in favor of the value of fat. The importance of butter fat on account of the vitamins contained in it has been dwelt upon by many recent writers and need not be discussed in this connection.

Although it has repeatedly been shown that the carbohydrates may largely replace fat, yet that they can do so satisfactorily is denied by many. Orgler (11), for instance, speaks of the large absorption of fat, both from human milk and from cow's milk, and believes that children in whom the carbohydrates have to a great extent replaced this do not do as well when fed in this way. He maintains that the increase of the carbohydrates at the expense of the fat causes a loss of water from the system. He emphasizes the fact that animal experimentation has shown that a certain amount of fat is necessary, and points out the significance of the high percentage of fat present in breast milk.

Yet in spite of the necessity for the administration of fat, the actual employment of it often causes many difficulties. These may be overcome in different ways. Bessau (7) emphasizes the fact, already known, that it is not so much an excess of fat which is detrimental as the lack of a proper proportion to the other ingredients of the diet; and that the fat may remain in the food unaltered in quantity if the amounts of the other elements are correctly arranged. That the fat is better tolerated when an amylaceous substance has been added to the diet is well known. It is exemplified, for instance, in the employment of malt soup, and even in the simpler preparations where a cereal decoction is employed as a diluent instead of water. Regarding the action of starch there are various opinions. We need not enter upon them in this connection. It is probable that there is more than one method in which the favorable result is obtained. The subject is ably discussed by Bessau. In any event, the fact of its value remains; and did it lack proof, the experience of Czerny and Kleinschmidt would remove all doubt. These authors in a somewhat empirical but very successful manner devised a food which permitted the employment of a high fat percentage in combination with a percentage of carbohydrate also high, but with the protein reduced to approximately the amount present in human milk. They insist upon the great importance of having the relationship of the fat and the carbohydrate a fixed one. As soon as this relationship is altered, the results are not so good. They believe that the favorable results are to be ascribed in part to the driving off of the volatile fatty acids from the milk fat; in part to the admixture of an amount of flour equalling that of the fat; in part to the chemical alteration of the flour produced by the browning which occurs during the preparation, and in part to

the low percentage of protein present, the last being particularly important in weakly infants.

The proportions recommended by them consist of seven grams of butter, seven grams of flour, five grams of sugar, and one hundred grams of water, to be mixed with varying amounts of milk, according to the age of the patient. These figures may conveniently be rounded off to, say, twenty grams of butter, twenty grams of flour, and fifteen grams of sugar in three hundred grams of water; but, as stated, the relationship of the butter to the flour must remain unchanged. In the actual process of preparation, twenty grams of butter are placed in a pan and heated over a gentle fire until foaming takes place, and until any odor of volatile fatty acids present shall have disappeared. This requires from three to five minutes. Twenty grams of fine wheat flour are then added and the mixture again boiled over a gentle fire with constant stirring until the mass becomes thin and of a brownish color (four or five minutes). Now three hundred grams of warm water and fifteen grams of sugar are added. The whole is again boiled, rubbed through a fine sieve, and then mixed with the desired amount of previously boiled, cooled milk, and the whole kept cold until needed for use. The addition of salt is not necessary, as this is contained in the butter. For children under three thousand grams in weight one third milk is added to two thirds of the butter flour mixture. For those of three thousand grams or over two fifths of milk and three fifths of butter flour mixture are employed. Not more than two hundred grams to the kilogram of body weight (i. e., about three fluid ounces to the pound) should be given daily, and usually smaller amounts than this are required, owing to the high caloric value of the food. At the time of their report forty infants had been fed in this way, of an age varying from less than one month up to six months. Twenty-one children had a weight of three thousand grams or less. The results were surprisingly good, and the gain in weight and length was excellent. There was no meteorism; the stools were yellow and of salvelike consistence, usually acid, and numbered one to three daily; sometimes three or four, yet without any harmful effect. Any previously existing disposition to vomit was not increased, and those who had not vomited earlier did not show any tendency to begin it. Increase in weight did not always commence at once, but would do so presently, and then went on rapidly with but little interruption, resembling greatly the gain in weight in healthy, breastfed children.

The improvement in general appearance and condition of the infant was particularly striking. This was in sharp contrast to that of other infants who had been fed successfully by other methods. The improvement was especially noteworthy in the development of fat in the lower parts of the body. Naturally not all of the infants did well, but the success in general was greater than with any other method of feeding which the writers had previously employed. All the patients were subjects of malnutrition when treatment was commenced, and many had had chronic nutritional disturbances following the early employment of different sorts of artificial

nourishment, or as a result of infection of some kind. The results were particularly good in weakly and premature infants in the first three months of life, weighing less than three thousand grams. If any dyspeptic disturbance was present, they delayed with the beginning of the food until there was at least a subsidence of the symptoms to some extent; but waiting for a complete restitution to health was not in their experience necessary.

In a somewhat later article, Kleinschmidt (12) describes the later experience of Czerny and himself with the butter flour food. They had tried it now even in infants a few days old and in those weighing less than two thousand grams, and found that under these circumstances it was better to employ at first a mixture in which the seven per cent. of butter and flour was reduced to five per cent., and the five per cent. of sugar to four per cent. Later the strength of the original composition may be employed, but this should always be considered the maximum. So, too, in infants who have not quite recovered from a condition of vomiting or diarrhea, or in whom for any reason there may be some doubt about the advisability of giving the food, it is well to begin with the weaker mixture.

The results of Czerny and Kleinschmidt's experiments were so encouraging that confirmation was sought by numbers of other clinicians.

Berend (13) employed the butter flour mixture in a number of cases. He thinks this food is a positive proof of the teaching of Czerny regarding the injury which may be done by fatty acids. Circumstances compelled him to use cooking butter almost spoiled, but the results were good. It sometimes takes a week or more before increase in weight commences.

Rietschel (9) showed by repeated trial the superiority in the very young and underweight subjects of fat mixtures as compared with those of milk, cereal and sugar, containing but little fat. He had very successful results with the Czerny-Kleinschmidt food modified to a certain extent.

Ochsenius (14) gave the butter flour mixture in 203 cases, always maintaining the relationship of butter to flour which had been insisted upon, but varying the proportion of the sugar to some extent. He completely confirms the claims made for the favorable action of the diet.

Stolte (15) tried the food thoroughly and fully agrees with the claims that it is especially useful in young and in premature infants of low weight. An important element is that it supplies enough nourishment; which is frequently not true of other food preparations. Its employment may be continued indefinitely. His metabolism experiments are of particular value, showing, as they do, that in spite of the comparatively small amount of nitrogenous material given, there was a positive nitrogen balance in every instance in which the tests were made. The high percentage of sodium chloride in the food, coming from the salted butter, appears to produce no disturbance in the water of the tissues.

Türk (16) tried the butter flour in sixty infants. His results were good on the whole, although there were eight who failed to thrive.

Thiemich (17) used it in about eighty cases with

very favorable results. He corroborates Czerny and Kleinschmidt in practically every detail. He refers to the belief that a diet rich in fat will make symptoms of the exudative diathesis worse, but did not find this to be the case with the employment of the mixture.

Friese (18) fed seventy infants with the butter

employed them in thirty-one cases with excellent effect. As already stated, he does not believe that the existence of volatile fatty acids has anything to do with the great advantage of the food, inasmuch as in his preparations he took no pains to dispose of these. He found the diet very useful in atrophic babies, and good in persistent cases of regurgita-

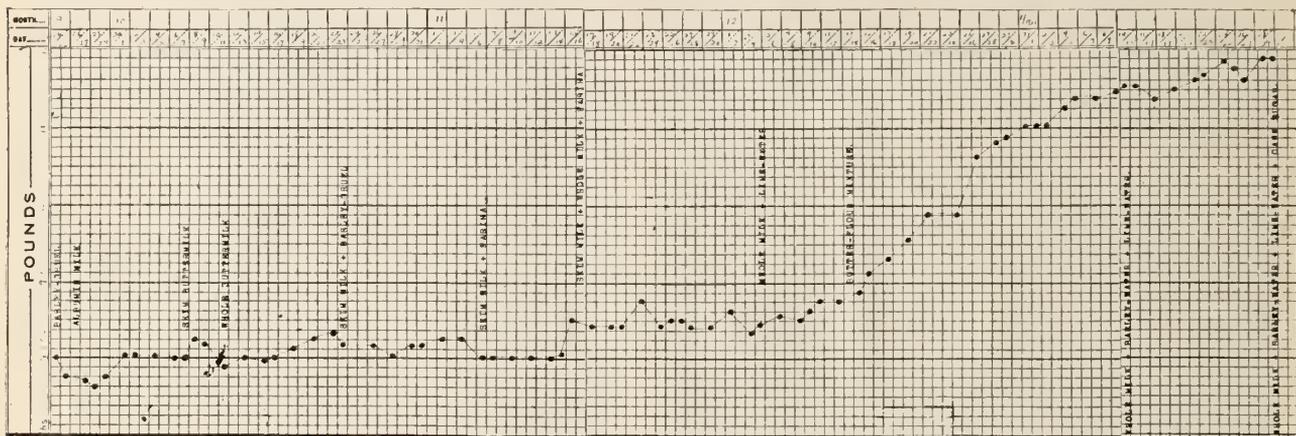

FIG. 1.—Weight chart of the Children's Hospital of Philadelphia. Case R. J., aged three weeks; admitted September 24, 1920.

flour food with results for the most part good, and he regards the formula as a great advance in infant feeding. Some experiments in which the butter was cooked but the flour not produced bad results, an indication that the browning of the flour is important.

Langstein (19) has in his own experience confirmed the value of the butter flour food in a large number of weakly infants who had not advanced

tion and vomiting; but does not think it suitable for the newborn. He agrees with Czerny and Kleinschmidt that there must be a certain fixed relationship between the fat and the carbohydrate, which should approach that present in human milk; viz, 1:1.7; and insists that it is important for success in infant feeding that fat should be present in sufficient quantity.

Bessau (7) found repeatedly that in the prepara-

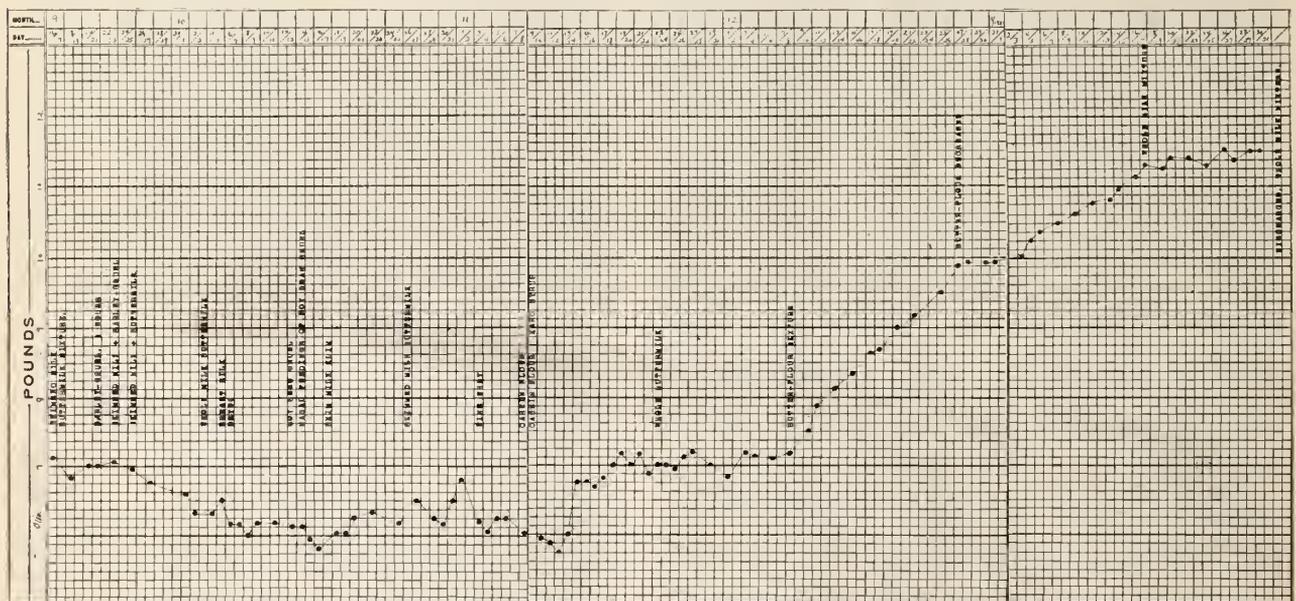

FIG. 2.—Weight chart of the Children's Hospital of Philadelphia. Case R. L., aged three months; admitted September 16, 1920.

with other methods of feeding. There may be, of course, bad as well as good results. He questions whether the value of the food depends upon the driving off of the volatile fatty acids.

Moro (8) prepared two formulae, based on the Czerny-Kleinschmidt butter flour mixture, and em-

tion of the butter flour mixture it was of the greatest importance to brown the substance.

Plantenga (20) used the food in thirty-one cases, with excellent results in most instances. He found, as did others, that some cases of eczema were benefited by it, these being clearly instances where that

disease depended upon defective nutrition. Some others were made distinctly worse, these probably being instances intolerant to a high percentage of fat.

Friedberg (21) employed butter flour in seventy-two cases and found it very efficacious in most of them. He reports some bad results, some of which he admits were not to be attributed to the food, while in other cases he would hold it responsible. In some of the patients who did badly it seemed sufficient merely to reduce the amount of sugar in order to obtain a good effect. He emphasizes the fact that proper judgment must be used in the selection of cases suitable for this nourishment, and with this, of course, all will agree.

Niemann and Foth (22) gave the food to sixty-two infants, and failed to get good results in only

and of the condition of the stools must be made before selecting butter flour in preference to other methods of feeding, and it is better to begin tentatively with smaller percentages of fat and carbohydrate. He found the results excellent in the exudative diathesis. It appears, too, useful for the prevention of rickets.

Beck (24) tried the butter flour food in twelve cases, but with a modification of the original formula. He found the mixture useful where there had been no prolonged digestive disturbance which was followed by an intolerance for fat.

Oertel (25) also reported on twenty cases in which he had used a modification of the formula, employing buttermilk instead of whole milk. His results appear for the most part to have been good.

Goett (26) tried the mixture in fifty-five cases,

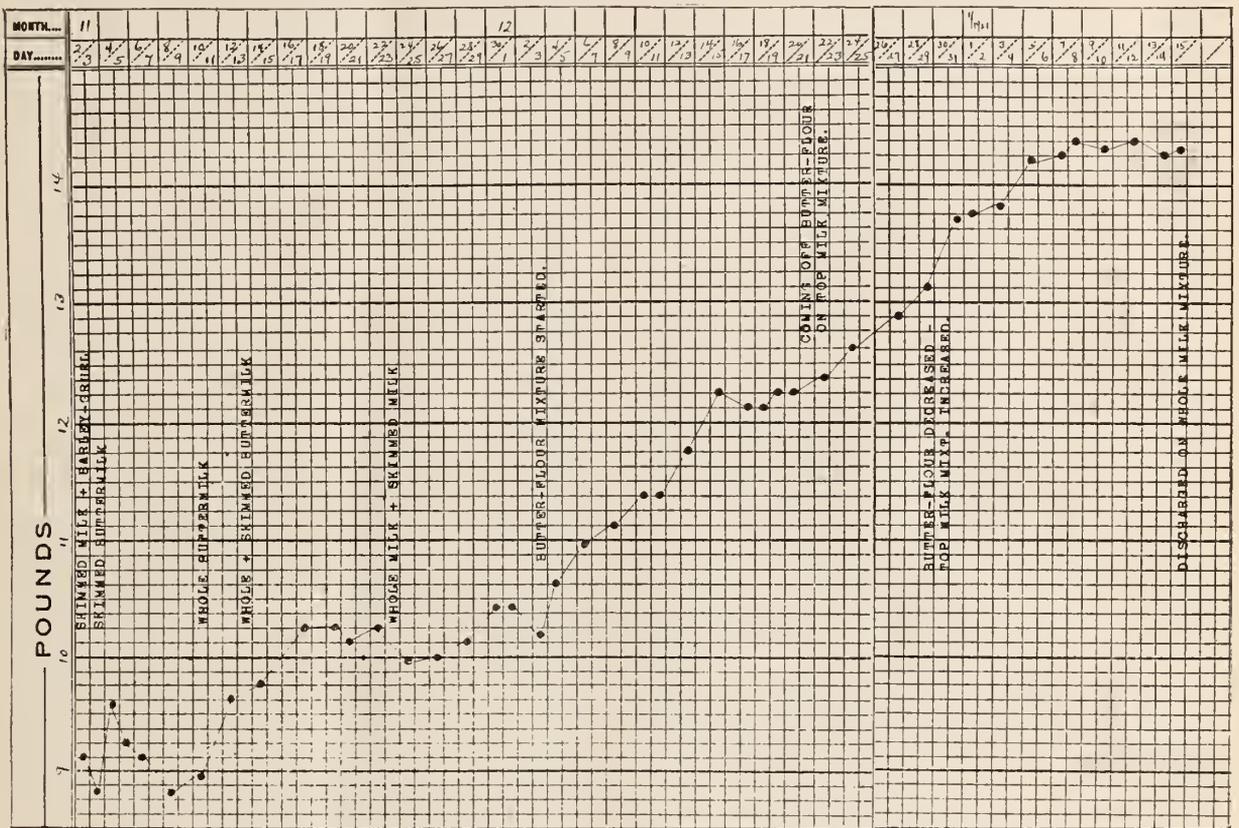

FIG. 3.—Weight chart of the Children's Hospital of Philadelphia. Case J. H., aged nine months; admitted November 2, 1920.

seven instances. They, too, urge the necessity of judgment in the selection of the cases, finding it unsuitable in acute diarrheal disturbances, in which all fat foods act badly. They, as do others, emphasize the importance of not giving too much, two hundred grams daily to the kilogram of body weight being the extreme maximum.

Reinach (23) has used the mixture in one hundred and twenty children who were either healthy or suffering from some nutritional disturbance. He found it useful in young healthy infants, combined with feeding from the breast. For premature infants and those with congenital asthenia exclusive breast feeding is to be preferred at first. In the case of those with subacute and chronic nutritional disturbances a careful study of the previous history

and found it especially useful in children much under weight when combined with breast milk feeding. He also found it of service in older children in combination with malt soup feeding.

Pfandler (27), in discussing Reinach's paper, referred to the fact that among the Tyrolese peasants it had been the custom for many years to employ a browned flour gruel (*Brennsuppe*) for the feeding of infants.

Timm (28) fed forty infants with the mixture and considers it a valuable food. He agrees with others in stating that it is not suitable for all cases of infants with nutritional disturbances.

Oswald (29) used the butter flour mixture for forty-five infants of whom seventeen were premature. In some of them the results were remark-

able, and only comparable to the use of human milk. He has had only one bad result, and thinks the food is a very valuable one.

Feer (30) stated that he had given the food in numerous cases with excellent results, particularly in the delicate, poorly nourished infants. He had seen rickets develop under its administration, but this is equally true of other methods of feeding.

Wieland (31), in discussing Oswald's communication, stated that there was no question about the favorable results which could be obtained, but he warned against considering it a perfect food which was suitable to replace human milk.

Reber (32) found the mixture unsuitable in severe cases of dyspepsia with rapid loss of weight and toxic symptoms, but had good results in other conditions, especially in disturbance of balance, atrophy, and decomposition.

Rhonheimer (33) points out that the Czerny and Kleinschmidt diet was not intended for a food for acute severe dyspeptic disturbances, but to be given only during or after recovery had commenced; and he thinks that in forming any judgment of its value, the directions for preparation given by the authors should be strictly followed, and the selection of cases also, as indicated by them. Its administration should be begun cautiously in the doubtful cases during recovery from severe digestive disorders. He says that the diet does not prevent the development of rickets, but that no one has ever said it was equal to nourishment with human milk.

Jacki (34) reports an epidemic of dysentery occurring in a number of infants fed upon the butter flour food, this being traced to contamination probably from a nurse infected by the disease. She thinks that final sterilization should be employed. This experience, of course, does not militate in any way for or against the value of the food.

Müller and Brandt (35) compare the composition of the butter flour mixture with the older fat mixtures of Biedert, Backhaus, and Gärtner. They modified the old ones by the addition of browned flour, but omitted the driving off of the volatile fatty acids by heat, and found by clinical experience no essential difference in the result. They feel that the butter flour food is a return to the old fat milk mixtures.

Wolff (36) tried the food in a number of cases, with excellent results, and corroborates the statements of Czerny and Kleinschmidt in every detail. He had good results in one case with symptoms of pylorospasm. He found it beneficial also in some cases in children of from two to four years with malnutrition.

The only unfavorable report appears to be that by Rosa Lange (37), who employed the food in thirty-four infants. While admitting the good results obtained by others, her own were not very satisfactory, there being more failures than successes. This can only be explained partly on the ground that a number of modifications of the Czerny-Kleinschmidt mixture were tried, not such as were proposed by the original describers, and chiefly because, as she admits, the clinical material was of a particularly unfavorable nature, many of the cases being evidently clearly unsuited for this form of

nourishment, if one follows the indications outlined by Czerny-Kleinschmidt. She speaks of what appears to be the unnecessarily high caloric value of the food, but found that a decided dilution of it was accompanied by continued loss of weight. Mixtures in which buttermilk replaced the milk were equally, for the most part, without good result.

Our own experience with the butter flour mixture covers its employment in the feeding of thirty-two infants. We have, for the most part, followed the technic of preparation given by Czerny and Kleinschmidt, and the amounts of the ingredients which we have usually employed consist of butter twenty grams, flour twenty grams, sugar fifteen grams, and water three hundred grams. Emphasis should be placed upon the necessity of following closely the method outlined by the German authors, especially in the browning of the flour. For convenience in making the mixture in the home we have estimated the various amounts of the ingredients in tablespoons. Thus it is sufficiently accurate to use two level teaspoonfuls of melted butter, two and one half level tablespoonfuls of flour, and one and one half level tablespoonfuls of sugar to ten fluid ounces of water.¹ All those who have used the food are insistent that the butter and the flour should be maintained in the correct ratio; that is to say, that in whatever manner the mixture may be modified, the amounts of butter and of flour should remain equal. If this caution is observed many different strengths of the mixture may be employed. Indeed, we found it of considerable advantage in certain cases to reduce the amounts of butter and of flour to less than twenty grams each to three hundred c. c. of water. In infants in whom there was evident fat intolerance, or who were convalescing from a severe intestinal infection or indigestion, the mixture could be started earlier than could otherwise have been done if only ten grams of butter and ten grams of flour were used with three hundred c. c. of water. The amounts of these two could be increased later. In some cases the sugar should be decreased in amount or omitted entirely. Again, one to three feedings of butter flour mixture a day were sometimes given as substitutes for the ordinary cow's milk mixtures which constituted the other feedings; and we have occasionally alternated it with breast feedings, as has been successfully done by others.

Czerny and Kleinschmidt recommended, as we have stated earlier, that in young infants and in those in whom the body weight is under three thousand grams (six and one half pounds) a mixture should be made of two thirds of the stock solution with one third of milk; in older infants three fifths of the stock solution with two fifths of milk. Other proportions of stock solution and of milk may, however, be employed at discretion. In certain cases we found it preferable to use skimmed milk in place of whole milk. In other words, it is quite simple to manipulate the percentages of fat, carbohydrate and protein in this food as the indications

¹We wish to express to Miss B. L. Mamby of the Children's Hospital of Philadelphia our appreciation of her care and interest in the preparation of the butter flour mixture, her determination of the measurement equivalents, and her preparation of the weight charts which accompany this communication.

arise, always, however, maintaining the fixed relation of the butter to the flour.

We attempted to determine the percentage strength of the elements of the mixture as finally given to infants, but encountered some difficulties. In the calculations the substances used were considered to have the following ingredients (38):

	Fat percentage.	Carbohydrate percentage.	Protein percentage.
Butter	85.00	0.00	1.00
Flour	1.40	76.40	7.90
Sugar	0.00	100.00	0.00
Milk	4.00	4.50	3.50

Using these figures as a basis the stock solution should contain about 5.75 per cent. of fat, ten per cent. of carbohydrate and 0.5 per cent. of protein. Analysis of this stock solution after it had been cooked was kindly made for us by Dr. Leon Jonas, of the Pepper Medical Laboratory of the University of Pennsylvania. This showed that the fat percentage as calculated was too high, and that the stock mixture contained only about five per cent of fat, owing to the loss of the volatile fatty acids by evaporation. Inserting this correction, one fluid ounce of the stock solution may be said to represent 26.6 calories. Based upon Dr. Jonas's analysis, the mixture containing two thirds of the stock solution and one third milk may be estimated as representing approximately fat 4.6 per cent., carbohydrate 8.2 per cent., and protein 1.5 per cent., with a caloric value of 24.6 to the fluid ounce. That containing three fifths of the stock solution and two fifths of milk similarly contains 4.6 per cent. of fat, and 7.8 per cent. of carbohydrate and 1.7 per cent. of protein, with a caloric value of 24.3 to the fluid ounce. Calculation of other strengths of the stock solution and of various mixtures with milk may readily be made.

Some of the probable reasons for the favorable results following the use of this combination of butter, flour, sugar and milk in infant feeding have already been pointed out. Mention should be made again of the form of fat supplied in this food. To say that there is a biological difference between human and cow's milk does not satisfactorily explain the fact that an infant whose digestion will tolerate a certain amount of human milk fat will not necessarily bear an equal quantity of fat from the mammary secretion of another animal. The most important difference which chemistry has shown us in the composition of the fat of human milk and of cow's milk, respectively, consists in the greater proportion of volatile fatty acids in the latter. In human milk these acids (butyric, caproic, caprylic and capric) constitute about two or three per cent. of the total fat, while in cow's milk they are present in several times that amount (39). In milk the volatile fatty acids are in combination as glycerides, and in this form are not liberated unless heated to over 275° C. The acids themselves, however, are soluble in hot water and can be distilled with steam at normal atmospheric pressure (40). In butter the volatile fatty acids must be present in looser combination than as glycerides, or may even occur as uncombined acids, because they are readily driven off by cooking. Their odor is easily recognized when butter, and especially ran-

cid butter, is heated to the point where it bubbles. Furthermore, Dr. Jonas found that the fat of the stock solution after cooking consisted entirely of neutral fat, and that no trace of fatty acids was discoverable. Whatever, then, may be the cause of the good results produced by the butter flour mixture, and whatever the relationship which the volatile fatty acids may bear to this, it is at least certain that the results are good and that in the food as prepared by Czerny and Kleinschmidt these volatile fatty acids have been removed.

We have, as stated, fed thirty-two infants with the butter flour mixture. For the most part the cases have been selected from among those infants who had not seemed to thrive when fed with the more commonly employed simpler modifications of cow's milk. These were the infants whose digestive capacity did not permit them to metabolize sufficient fat, carbohydrate and protein, as ordinarily offered them, to produce a satisfactory gain in weight. Such a condition is variously diagnosed as gastrointestinal indigestion, malnutrition, disturbance of balance, or dyspepsia, depending upon the nomenclature adopted and the severity of the symptoms. We found that the mixture, like other foods, had its indications and contraindications, and that the success of feeding depended upon the proper selection of the cases. There are certain digestive disturbances which appear to contraindicate the employment of the food. Thus, when from any cause there was considerable diarrhea or a sudden distinct loss of weight, or the intestinal derangement was one accompanied by fever, the Czerny-Kleinschmidt mixture not infrequently appeared to aggravate the symptoms. The severer forms of malnutrition, where the tolerance for any form of food is low, may grow decidedly and rapidly worse when butter flour mixture is used. The food should be given cautiously, if at all, to infants suffering from infantile atrophy (athrepsia, decomposition). Other conditions which might not be expected to respond favorably to it nevertheless did so in certain instances. Among these may be mentioned some cases of eczema and certain instances of gastrointestinal indigestion in which vomiting was a marked feature. Contrary to the experience of some of the investigators we found pyloric stenosis benefited by the butter flour mixture in two instances. We found, however, that it was the infant whose low body weight was due to a failure properly to metabolize sufficient cow's milk fat who responded most favorably to the Czerny-Kleinschmidt food.

In spite of the high fat content of the butter flour mixture vomiting seldom occurred. Of our thirty-two infants in only two did vomiting follow as a marked symptom. Neither of these responded favorably to butter flour feeding. Nine infants vomited once or twice during the first two or three days on which they received the mixture; but five of these nine had previously been vomiting foods more than they subsequently did the butter flour. Four infants who had been suffering from repeated vomiting stopped this when they were given the new preparation. Two of these were the babies already referred to with distinctly visible gastric peristaltic waves, one of whom had been fed unsuc-

cessfully upon breast milk supplemented by a cow's milk mixture, and the other upon a corn syrup and buttermilk combination.

The stools of the infants taking the food were rather characteristic. They were of a light yellow color, resembling more the canary tint of the breast-fed baby's stool than they did that of the stool of the infant receiving cow's milk. The odor was not offensive, but was somewhat aromatic. In consistency the stools were soft, and at times lumpy rather than smooth. Mucus was seldom present, although a shiny appearance resembling it was not uncommon. Under the microscope starch was almost invariably found, and it could also be demonstrated by the iodine test. The usual impression received when employing the method recommended by Morse and Talbot (28) was that about one half of the fat of the stool was present as a soap, and that the remainder was equally divided between neutral fat and fatty acids. Occasionally the last two were not found under the microscope. The stools were acid in reaction, but apparently not excessively so, and it was only infrequently that the buttocks became irritated. In number the movements varied from one to three in twenty-four hours, and even infants who were doing badly on butter flour feeding did not have more than five stools a day.

The gain in weight in infants who thrive upon the butter flour food is usually satisfactory and often really wonderful. We exhibit three illustrative weight charts which speak for themselves. Although Czerny and Kleinschmidt state that the gain did not begin at once, it has been our experience that the favorable influence on weight was shown very promptly, and that after twenty-four hours of butter flour feeding infants, whose weight had been previously stationary or decreasing, started to exhibit a steady increase in weight which continued as long as the food was used. The average gain on each day was about one and a half ounces. Some of our patients gained in weight so rapidly that the result, at the beginning, could only be explained on the theory of water retention. Thus one baby gained seven ounces over the first night, and another twenty ounces in six days. The majority of our patients received the butter flour mixture for a month or longer. The greatest length of time during which we have used the food in any individual case was forty days, in which time the baby gained fifty-four ounces. The stopping of the butter flour diet was usually done simply because the progress had been so excellent that it appeared time to send the infant to its home. In some of our later experiences we have had the mothers taught by the nurse how to prepare the food in their own homes—a matter which did not seem to be at all difficult for women with average intelligence.

The amount of the mixture fed to the infants depended on their age and weight, and did not differ materially from that commonly employed with other foods. Czerny and Kleinschmidt and other German clinicians recommend that from one hundred and twenty to two hundred grams of the food should be given daily for each kilogram of body weight (one and three quarters to three fluid ounces to the pound). In our own cases we often exceeded three

ounces to the pound without deleterious effects. From seventy-five to ninety calories of the food to the pound of body weight a day were usually required in our cases. In one instance from one hundred and ten to one hundred and twenty calories were well tolerated for the month. Occasionally satisfactory gain occurred when but sixty calories to the pound of body weight were given daily.

Two symptoms were observed in the babies while taking the new food, which were so noticeable as to be worthy of remark. Without offering any explanation of these phenomena, it may be stated merely that sweating was present in almost all the infants, and, as a consequence of this, sudamina developed. This latter symptom was so constant that it was spoken of in the hospital as the butter flour rash. The sweating and the rash have not been mentioned by other authors, so far as we know. That the sweating had nothing to do with the development of rickets, is evidenced by the fact that no other symptoms of this condition made their appearance. It may be stated, too, that observers in general have seen no tendency to any special inclination to the development of rickets in infants fed upon this diet.

The removal of babies from butter flour feeding is not a procedure to be accomplished quickly. We have not been successful in suddenly stopping it and at once substituting all the feedings with an ordinary cow's milk mixture containing a high fat percentage and a strong cereal decoction. When this plan was attempted diarrhea and vomiting and consequent loss of weight frequently developed. If, however, a weaker cow's milk mixture made with a barley water diluent was used, such, for instance, as one containing fat two per cent., carbohydrate six per cent., and protein two per cent., one bottle of this substituted for one of the butter flour food, then in two or three days a second bottle, and so on, indigestion did not occur and gain in weight often continued throughout the transition stage.

The average age of the infants whom we fed on the new food was four months, the youngest being two weeks old and the oldest one year. The average weight at the beginning of the feeding was eight and a half pounds; the extremes being five and a quarter pounds and fourteen and a half pounds. Eight infants weighed each six pounds or less. Of the thirty-two infants to whom we fed the butter flour food twenty-three responded favorably. These patients not only gained weight, but also showed improvement in their general condition, in that the digestion was good, the turgor of the tissues increased, the maximum amount of sleep was obtained, and contentment and satisfaction with the food were notably manifest. Of the infants doing well on the mixture three had eczema, two pylorospasm, one was a cretin, and one a Mongolian idiot.

In analyzing the subsequent histories of the nine infants who did not improve upon butter flour feeding, it seems fair in seven instances to observe that the type of feeding was not in itself responsible for the failure. Thus one baby died suddenly two days after the diet was commenced, nasal diphtheria developed in one, and bronchopneumonia in one, while

one infant was suffering from tuberculosis of the lungs and bronchial glands, one from chronic basilar meningitis, one from congenital syphilis and hydrocephalus, and one from a low grade peritonitis due to a ruptured appendix. In one of the two remaining babies the food was contraindicated and should not have been employed, as the patient had been exhibiting fever, diarrhea, and rapid loss of weight. The other baby was a rather typical case of fat indigestion and improved at once when removed from butter flour feeding and given a skimmed milk mixture.

The conclusions to be drawn from our own experience and that of others are so obvious that it would appear unnecessary to formulate them at any length. The two great lessons which we are taught are, first, that when fed with the butter flour food infants may often tolerate fat in a manner which can be accomplished probably by no other means yet known to us; and, second, that the truly remarkable results which often follow are a strong proof of the great need which the infant's economy possesses for a food containing a sufficiently large amount of fat.

Diagnosis of Summer Diarrhea*

By J. CLAXTON GITTINGS, M. D.,
Philadelphia.

Nothing offers greater opportunity for difference of opinion than an attempt at a classification of intestinal disorders in early life. It would probably be difficult to find two pediatricists agreeing absolutely on any one selection.

Summer diarrhea may be considered as occurring in two main types, one due primarily to infection of the intestinal wall and the other due to a disorder involving the intestinal contents. If these basic distinctions are admitted, it will be agreed at once that hard and fast lines of demarcation between types often are difficult or impossible to draw and that mixed types are encountered not rarely.

The distinguishing feature of type one is that bacteria, usually introduced in food, drink or by contact with infected articles, invade the wall of the gut and set up definite anatomical changes. Type two may be viewed as a functional disturbance rather than a somatic disease, since the basic disorder involves the intestinal contents rather than the intestinal walls. It is an open question whether this disorder begins as a disturbance of digestion due to a perversion of normal digestive function resulting from the enervating effects of heat, physical exhaustion, or other cause; or whether bacteria play the most important rôle in inaugurating unusual forms of fermentation or by causing an excess of what may be called normal bacterial activity.

*Read before the Philadelphia County Medical Society, May 11, 1921.

The subject offers such intrinsic difficulties in its solution that a decision at the present time is impossible.

Infectious diarrhea has two chief synonyms, ileocolitis and dysentery. The latter term suggests an unvarying relationship to the *Bacillus dysenteriae*. Many attempts have been made to prove the agency of other types of bacteria, notably the gas bacillus, various forms of streptococci, and *Bacillus coli*, *Bacillus pyocyaneus*, and other bacilli. It is difficult to determine whether these organisms are primary or secondary invaders, so that no positive statement can be made as to the exact importance of any, except the *Bacillus dysenteriae*. Although hot weather, and especially the combination of heat, humidity and stagnant air, undoubtedly predispose to any of the diarrheal diseases, the infectious form is seen occasionally in cool weather. For example, a small epidemic of a mild type occurred during March, 1921, in the children's ward at the University Hospital, in which the *Bacillus coli* was the predominating organism. Ileocolitis also seems prone to follow other diseases, such as bronchopneumonia, or to occur in infants who have suffered from chronic intestinal indigestion and its consequent malnutrition. In typical cases the infecting organisms invade the wall of the gut early, causing infiltration of the mucosa. The inflammation spreads to the submucous layer and involves the solitary lymphatic nodules. The latter may break down and ulcerate, resulting in small punched out cavities. In other severe types the superficial infiltration may be followed by necrosis which leaves irregular ulcers. Secondary to the lesion of the bowel we find enlargement and congestion of the mesenteric lymph nodes and it is probable that bacteria may reach the blood stream by transfer to the thoracic duct from the mesenteric lymphatics. In this way can be explained secondary infections which sometimes occur in other parts of the body, such as bronchopneumonia. Since the disease is a systemic as well as a local infection we usually find parenchymatous degeneration to a greater or less extent in liver, kidneys and spleen. True nephritis rarely results.

The second or functional type of diarrhea probably depends more definitely upon atmospheric conditions than does the infectious type. Not only does heat exert its debilitating effect upon the child and especially upon the infant in its first year, but it also favors the development of various organisms in the food before it is consumed, such as those in milk and raw fruit. The direct agency of bacteria within the intestine, however, has never been placed upon a satisfactory basis and it is hard to avoid the conclusion that various types may act upon the food residue, but that defects in the mechanism of digestion have prepared the appropriate pabulum. It is also certain that the infant or child who has been subject to intestinal indigestion is especially prone to these functional forms of summer diarrhea.

Indigestion *per se* from carbohydrate or fat apparently explains many instances of moderate diarrhea occurring at any season, in which the special agency of bacteria cannot seriously be called into question. These do not belong to the category of

summer diarrhea although, when they occur in summer, there can be little doubt that they furnish ideal conditions for bacterial activity. In another class of cases, bacterial toxins are developed in the food, such as milk, before its consumption, and act as acute and virulent poisons.

The intestinal lesions in the functional form of diarrhea show a wide variation in intensity, but the chief change consists in a superficial catarrhal inflammation. It would seem that this is due, for the most part, to the irritation of abnormal or excessive products of fermentation, such as the lower fatty acids, rather than to the action of bacteria *per se*. Secondary involvement of the gut resulting in a true infectious diarrhea probably occurs quite frequently.

SYMPTOMATOLOGY.

This may be given in the form of a comparison by grouping, first, those symptoms which are more or less common to both types of diarrhea, and secondly, those which show material points of difference. It must be understood also that the usual differences in degree which are seen in mild, medium or severe cases, cause pronounced variations in the symptomatology.

Onset.—Both forms of diarrhea may be preceded by symptoms of indigestion, but as a rule, the onset in both types is sudden, at least during hot weather.

Toxemia.—Toxemia will be present in both types, depending upon their severity. As a rule, however, the patient with functional diarrhea will show a higher initial temperature and more severe toxic symptoms than are seen in ileocolitis. In the latter, toxemia increases at a time when the functional type begins to show improvement. The severe toxic cases of functional diarrhea show a suggestive facies, apathetic or stuporous, with dull, sunken eyes. In others there may be restlessness or even convulsions at the onset, but drowsiness or stupor soon follows.

Vomiting.—Vomiting is not as common in the infectious as in the functional type. In the former it usually occurs chiefly as an initial symptom, ceasing when the stomach and duodenum are emptied of food. In the functional type, vomiting may be severe and prolonged although it rarely persists throughout the attack and may be absent entirely.

Anorexia.—Anorexia is common in both types but usually is more pronounced and protracted in the infectious diarrheas.

Prostration.—Prostration at first depends upon the severity of the toxemia and of the diarrhea and vomiting. It is likely to be more severe at first in the cases of functional diarrhea; later it is equally well marked in the infectious type. As an index to the degree of actual prostration the pulse usually is a reliable guide. It may be reiterated that a distinguishing feature between the two types of diarrhea is that in general the functional type tends to an acute course with recovery or death, while infection of the intestinal wall speaks for chronicity.

Restlessness.—As an early symptom restlessness depends upon toxemia as well as upon abdominal pain. Later we may expect to find it chiefly in the infectious type in which the intestinal lesions are more provocative of hyperperistalsis.

POINTS OF DIFFERENCE.

The characteristics of the diarrhea itself furnish the chief diagnostic points of difference. For the first six to twelve hours both types are likely to show merely a rapid emptying of the gut with more or less evidence of indigestion with serous transudate. There usually follows, in the functional type, marked flatulence with a variegated type of stool, six to twelve or more a day, of foul odor, usually acid in reaction, and often causing irritation to the skin of the buttocks. The offensive odor often ceases by the second or third day and mucus appears. In favorable cases with suitable treatment convalescence begins at this stage, and may be complete within ten to fourteen days or sooner. In debilitated or very young infants death may come in two or three days. In others the acute attack may be succeeded by chronic intestinal indigestion or a secondary ileocolitis. The ultimate mortality in such cases in hot weather is extremely high.

In infectious diarrhea, after the initial emptying of the bowel, the stools become more frequent and less copious, consisting chiefly of mucus, epithelial and bacterial detritus intimately mixed with varying amounts of blood, which is darker in color than fresh blood. The reaction often is alkaline. Preceding each stool usually there is abdominal pain, and the rectal tenesmus during and after the stool is one of the most characteristic symptoms. In mild cases the blood may almost disappear after a few days but an excess of mucus continues throughout the acute stage. In severe cases blood persists for a longer period. When ulceration of the follicles occurs, after the acute stage of congestion has passed, the stools become less frequent, dark brown or green in color, with offensive odor. Blood is seen occasionally but not in large amounts. Mucus or mucopus is always present and, microscopically, large numbers of round cells can be seen.

To sum up, in functional diarrhea flatulence and foul odor to the stools are early symptoms but the number of stools soon tends to diminish and blood is seldom seen. Abdominal pain occurs at first but is not a symptom of major importance. In ileocolitis the stools consist in large part of mucus, and the odor may not be especially offensive. Frequency is marked and persistent, blood is a characteristic finding, while abdominal pain and rectal tenesmus are present in a majority of cases.

Fever.—In both forms there is an initial rise of temperature which may be higher in the functional type but in the average case soon tends to fall and assume a slight or moderate irregular range. In severe cases fever may persist and in others a recurrence is often seen before death. In ileocolitis, on the other hand, fever is constant throughout the active stage, tending to range between 100° and 102° or more for at least ten days, and, in protracted cases, simulates the temperature of typhoid fever.

Dehydration.—In every case of severe diarrhea with rapid loss of weight there follows to a greater or less degree the condition known as dehydration. In this there is a diminution of the blood volume with increased viscosity, a retardation in the flow of blood in the peripheries, stagnation of the red cor-

puscles in the capillaries, and an increased concentration of solids in the blood serum (increased refractive index).

Marriot believes that all of these symptoms can be explained in large part on the basis of a severe water loss from the body. Clinically, the skin and subcutaneous tissues give every evidence of dryness. The diminution in the output of urine, which always occurs, probably explains in part the secondary symptoms of intoxication which occurs *pari passu* with the dehydration. Acidosis at times is another factor in the production of the toxic state. The dehydration and toxemia are likely to be more marked in the functional than in the infectious type of diarrhea, because the water loss usually is greater in the former type. This forms additional evidence in favor of Marriot's contention.

Two rare special forms of diarrhea may be described, as follows:

Membranous colitis.—This form of ileocolitis usually resembles the severe forms of functional diarrhea in the sudden onset, marked toxemia and high fever. The stools are watery at first but blood appears early and abdominal pain and tenesmus are pronounced, the latter often leading to prolapsus ani. On the wall of the prolapsed gut sometimes can be seen patches of pseudomembrane, and the stools may contain shreds of it. In some cases there may be slight constipation at the onset so that the toxic symptoms, vomiting, delirium and stupor, may simulate meningitis, and the true nature of the attack may be masked. Sometimes death may follow before diarrhea sets in.

Cholera infantum.—Cholera infantum, a form of functional diarrhea, usually is given a separate place because of its special characteristics. As a rule it occurs in babies who have been suffering from chronic intestinal disorders. The first symptoms are prostration and fever, soon followed by severe and protracted vomiting and a profuse watery diarrhea. The stools are as frequent as in the worst cases of ileocolitis but, after the initial emptying of the gut, consist of serous transudate rather than mucus. The reaction is acid at first but soon becomes alkaline. Tenesmus is rarely seen, and as the disease progresses the fluid runs from the bowel without any control by the sphincter. The abdomen is sunken. Tenderness and rigidity of the walls are lacking. In such cases dehydration of the tissues occurs early and becomes extreme and the loss of weight is shockingly rapid. The urine is scant, highly acid, and usually shows albumin. Death occurs in stupor, often within forty-eight hours of the onset.

Because of the excessive loss of fluid from the bowel, and the absence of any signs or symptoms of a severe inflammation or congestion of the intestinal mucosa, it has been suggested that cholera infantum may be a form of general toxemia rather than a specific affection of the intestinal tract. If this is true the loss of fluid evidences the attempt of the organism to eliminate systemic toxins rather than to get rid of a local intestinal irritant.

DIAGNOSIS.

Summer diarrhea usually does not offer any difficulty in diagnosis except in the attempt to differen-

tiate its two forms. Several other conditions must always be remembered, however, as a failure to recognize them may have most serious consequences.

The appearance of blood in the stools in early life, but especially in infancy, should always suggest the possibility of intussusception. If vomiting and abdominal pain or discomfort are present and if enemas bring only mucus and a small amount of fecal matter, intussusception becomes the most probable diagnosis. Confirmatory symptoms are the absence of fever and the presence of a sausage-shaped tumor, usually in the right iliac fossa. At times the tumor can be felt best by rectal examination.

The presence of vomiting also should always suggest the possibility of meningitis, which often begins with a moderate diarrhea. Pneumonia, pyelitis, and even otitis media also may be ushered in with gastrointestinal disturbances. In all of these diseases, however, the diarrhea rarely is severe enough to cause confusion with ileocolitis or functional diarrhea, and the characteristic symptoms of each disease usually are conclusive. Typhoid fever may simulate ileocolitis but again the diarrhea of the latter usually is much more severe than in typhoid.

Poliomyelitis in the preparalytic stage not rarely is diagnosed as enteritis and even more frequently in the abortive forms. From careful observation and the results of lumbar puncture it should be possible to reach a conclusion, although, in the absence of an epidemic of poliomyelitis, the decision is not always easy to make.

The relation of diagnosis to treatment rests upon the determination of three factors; a, involvement of the intestinal wall with a more or less specific type of organism; b, perversion of digestion in conjunction with more or less bacterial activity, and c, dehydration of the tissues. In the first, specific treatment may be tried but diet certainly plays a much less important rôle than in the second class. In the latter, dietary treatment is of extreme importance. If a predominating type of organism can be determined, the attempt can be made to secure a

change of intestinal flora by dietary procedure.

The occurrence of the third factor, dehydration, even in mild degree, at once gives an imperative indication for treatment. In the presence of a severe diarrhea, even before dehydration can be recognized clinically, appropriate measures for prevention should be inaugurated. Particularly is this true of infants whose nutrition has been retarded as a result of previous indigestion or other illness.

An analysis of one hundred cases of summer diarrhea at the Children's Hospital showed that thirteen were of the infectious type and eighty-seven of the functional type. The onset was recorded as sudden in every case in which the history was complete. Vomiting occurred as an initial symptom in sixty-nine per cent. of the infectious cases and seventy-one per cent. of the functional cases. Blood was present in the stools in all the infectious cases and to a slight degree in only eight per cent. of the functional cases.

Considering a maintained average temperature of 101° F. as febrile, fever was present in all of the infectious cases and in twenty-six per cent. of the functional cases; of the latter twelve and four-tenths per cent. only showed a rise immediately preceding death; bronchopneumonia was the cause of the fever in three and four-tenths per cent. and in nine per cent. the fever barely exceeded 101°. In only one case, therefore, was there any pronounced and protracted fever without demonstrable cause other than the intestinal affection.

The mortality was sixty-one per cent. in the cases of colitis and twenty-four per cent. in the functional types. Not directly connected with the subject, but of interest, was the average number of days that the patients had been sick before admission, twelve and one half days in the infectious type and eleven in the functional. In only one fifth of the total number were the patients brought to the hospital on or before the third day of the disease. This may explain in part the excessive mortality in hospital cases.

Use and Abuse of Drugs in Summer Diarrhea*

By JOHN F. SINCLAIR, M. D.,
Philadelphia.

To clear the way for the presentation of the first part of the title of this article, i. e., the use of drugs, let us at the very beginning consider the latter part of our subject, the abuse of drugs.

The drugs which have been most grossly misused are undoubtedly the laxatives, especially castor oil and calomel. These are of undoubted value when properly employed in appropriate doses, as an initial laxative, at the very beginning of a gastrointestinal attack, but when they are administered again and again, often every second or third day as is frequently the custom with some physicians, they unnecessarily deplete the system of the water and

mineral salts in which it stands greatly in need and weaken rather than support the bodily defenses.

Furthermore, in those cases which are first seen late in the attack after gastrointestinal disturbances have progressed beyond the acute stage, it is frequently ill advised to administer either castor oil, calomel, or other laxative, for the reason that the baby cannot survive if the reserves of water and salts are still further and rapidly depleted. In the case of castor oil it is also true that it tends to produce vomiting and that large or frequently repeated doses may cause sufficient irritation of the intestinal mucosa to bring about the appearance of blood in the stools quite apart from any inflammatory condition which may exist then or subsequently.

*Read before the Philadelphia County Medical Society, May 11, 1921.

Next to the laxatives the greatest misuse or abuse of a drug is in connection with the administration of opium. On the one hand, the laity and certain physicians press the use of opium, usually in the form of paregoric, to such limits, that it is not infrequent in hospitals with infant wards to receive patients who are suffering from unmistakable opium poisoning. Probably, however, the more frequent error is in withholding opium altogether when proper doses would allay excessive peristalsis and relieve pain. Excessive peristalsis accompanies and causes the very frequent diarrheal stools, while lessening peristalsis puts a stop to the loss of water and mineral matter. The main indications for the use of opium then are to stop excessive peristalsis and to relieve pain. The main contraindications to the use of opium are found in an intestinal tract which has not been completely evacuated, in infrequent and foul stools, in the early stages of acute cases, and in those cases accompanied by high temperature, cerebral symptoms, and scanty elimination. It is a valuable drug when properly employed at the proper time and in the proper place. It has, however, been frequently used unwisely.

Turning now to the use of drugs in summer diarrhea, presupposing an infant with a gastrointestinal disease, how shall we proceed in so far as the administration of drugs is concerned. The diagnosis is of first importance. What are we dealing with? An irritation, probably largely mechanical, of the digestive tract, or, is it an inflammation of stomach and bowels? If the former, what should be the plan of action?

Where the symptoms and signs point to an irritation rather than to an inflammation of the intestinal tract the procedure is simple. A prompt and energetic use of castor oil, one to four drams according to the age of the child, or calomel in divided doses from one tenth to one quarter of a grain at intervals of one half hour to one hour, until a grain has been given, followed by calcined magnesia, five to thirty grains, or milk of magnesia, half a fluidram to two fluidrams, is indicated and this medication should be followed by a period of temporary starvation. In the great majority of cases in which there is only the irritative or mechanical factor the patients will respond promptly to this simple mode of medication. Occasionally, either the subcarbonate or the subgallate of bismuth may be required for a short period in doses of ten to twenty grains every three hours, or dram doses of chalk mixture every two hours may suffice.

The inflammatory or infectious types are unfortunately not always so readily amenable to treatment. Here in the acute cases the preliminary use of castor oil, or calomel followed by magnesia, is indicated and should precede brief periods of starvation as has been described above.

In the milder of these cases chalk mixture may be employed with advantage while the more severe cases call for the administration of bismuth subcarbonate or subgallate in full doses. If these cases do not promptly show an abatement of the diarrhea and especially if there are evidences of excessive peristalsis and pain, opium in the form of camphorated tincture five to fifteen drops, Dover's powder,

half a grain, or deodorized tincture is indicated. In the case of marked tenesmus the starch enema with five to ten drops of tincture opii to the ounce of starch water is usually efficient in relieving this distressing symptom.

If the inflammation is severe and extensive and the patient has difficulty in combating the infection it may become necessary to resort to stimulation. Probably the best drugs for this purpose are caffeine sodium benzoate one half to one grain, tincture of digitalis, one quarter to one minim, and brandy five to twenty minims well diluted in water. For very prompt but evanescent stimulation, as in a threatened collapse, camphorated oil (one or two grains in oil), hypodermically is generally employed. This must be repeated at hourly or two hour intervals.

Atropine has a distinctly stimulating effect on the heart, and in infants with subnormal temperature its administration tends to raise the temperature when used in connection with other appropriate and external measures, such as anointing with oil, wrapping in cotton, and supplying external heat by means of hot water bags, bottles, etc. Atropine as a cardiac stimulant in these cases may be given hypodermically in doses of from 1/1000 to 1/500 of a grain every three or four hours.

In the more severe and active forms of the inflammatory types under consideration it is not unusual to meet with varying degrees of acidosis brought about by the dehydration and loss of mineral salts previously referred to. To anticipate and prevent any such eventuality it is a wisely established practice to administer sodium bicarbonate in fifteen grain doses every three hours routinely to all infants who are more than mildly ill with inflammatory or infectious forms of gastrointestinal disease.

Should this prophylactic measure not be successful in warding off acidosis, as is sometimes the case, one must either give larger doses by mouth or administer it either intravenously or subcutaneously. The urine must be made alkaline and kept so. In using the intravenous or subcutaneous routes as much as fifty c.c. of a four per cent. solution of sodium bicarbonate may be administered at one time. This solution must be carefully prepared by sterilizing a four per cent. solution of carbonate of soda and then transforming the solution to the bicarbonate of soda by passing carbon dioxide from a Kipp generator, or a cylinder, through the cold solution until it is colorless to phenolphthalein. Even with all these precautions sloughing may result from its use.

Severe and prolonged attacks of inflammatory types of gastrointestinal disturbance frequently lead to more or less marked degrees of anemia which call for the administration in the convalescent period of such tonics and hematinics as iron and arsenic; Fowler's solution, one quarter to two minims three times a day well diluted, or the lactate or citrate of iron in doses of one quarter to one grain three times a day may be given orally, or the green citrate of iron in one quarter grain doses may be injected intramuscularly every other day alternating with sodium cacodylate three quarter grain, also intramuscularly, on alternate days.

Dietetic Management of Summer Diarrhea

By WILLIAM N. BRADLEY, M.D.,
Philadelphia,

Visiting Pediatricist, Howard Hospital; Visiting Pediatricist, Philadelphia Hospital; Instructor in Pediatrics, University of Pennsylvania.

Summer diarrheas are so distinctly and definitely preventable, that it seems advisable to consider for a moment the dietetic prophylaxis of the subject before proceeding to the management of the pathological condition. One need only call to mind the oft repeated statement that six bottlefed babies die to every one that is breastfed, to realize the tremendous immunity to disease which the breastfed infant possesses, and particularly is this true with reference to diarrheas. That a very large percentage of women can and will, with a little encouragement and advice, nurse their babies is proved by recent statistics of the prenatal department of the Starr Centre. Last year of 129 babies born consecutively under the care of this department, 128 were being breastfed at the end of the first month of life. This, almost one hundred per cent. breastfeeding, was among mothers living under the hardest possible conditions, and in an environment of poverty, ignorance and superstition. Obstetricians and maternity hospitals can do much to advance the cause of breastfeeding by encouraging the mothers to a persistent effort to do their part. The effect upon the baby's development and resistance of even a few months of breastfeeding cannot be overestimated. Early weaning should always be avoided in the summer months if possible.

A glance at the mortality statistics of any large city for the summer months of the last ten years shows the progress in baby saving which public education has effected. A cleaner milk supply, with a better understanding as to its care and handling, has very appreciably reduced the incidence of diarrheas and consequent deaths. Where artificial feeding is unavoidable it is important that the best possible milk be obtained and that it be prepared and cared for in the most sanitary manner. In the summer months all milk intended for infants should be brought to the boiling point before using. All additional food should be closely restricted by its suitability to the age and digestive capacity of the individual, always remembering that it is better to underfeed in hot weather than to chance the dangers of a digestive disturbance.

Regardless of the etiology of the various forms of summer diarrhea, the preliminary management conforms with but slight variation to one mode of procedure. At the first sign of disturbance the stomach and intestines should be cleansed immediately of all irritating substances, by means of a laxative or by colonic irrigation, or by both if necessary. All food should be withheld for a period varying from six to forty-eight hours, being replaced by boiled water, cereal decoctions, or saccharine tea and similar substances. If mothers could be taught to follow this simple procedure until the arrival of the physician, serious trouble might often be averted. In the case of diarrhea resulting from a simple gastric disturbance accompanied by stools, more or less

frequent, green in color, frothy, foul, and containing curds or undigested food, the routine outlined above is usually sufficient to relieve the condition, and a gradual return to the normal diet is readily effected.

According to the bacteriological etiology of the summer diarrheas, two types are distinguishable, the fermentative and the infectious. Both types may bear a distinct relation to bacteria. In the former, the bacteria are chiefly saprophytes which do not seriously injure the tissues, and in the latter they are chiefly parasites, which directly or indirectly injure the intestinal walls. Both types may be present and the distinction becomes an artificial one.

The fermentative or typical summer diarrhea is characterized by intoxication or infection, or both. It is due to a preponderance in the intestine of one form of bacteria, usually saprophytic, either acid forming or putrefactive. If the former type of bacteria are in excess, then the carbohydrate and fat elements in the food must be reduced or entirely withdrawn for a time. If the putrefactive are found to be in excess, then the protein element must be withheld. By far the greater number of diarrheas are caused by the excess of the former, the acid forming bacteria. The stools in this form of diarrhea are loose, green, acid and irritating, and may contain mucus.

The relief of the condition and the restoration of the digestive functions lie in suitable dietary management. Talbot states: it is possible in some instances to destroy the pathogenic microorganisms, or at any rate to diminish their number materially and inhibit their activity by the administration of antagonistic bacteria.

In the type of diarrhea under discussion, following the preliminary emptying of the intestinal tract, the withdrawal of food, and the substitution of a water diet, the return to a suitable diet must be undertaken cautiously. Beginning with cereal gruels, plain or dextrinized, broths, plain or thickened with cereals and meat fibre, proceed to a fuller diet as the condition of the patient, as indicated by the character of the stool, permits. Because of the constant tendency to relapse the quantity given should be small, the intervals long between feedings, and the strength much diluted. The return to milk should be delayed and when finally resumed it should be preferably in some form low in fat and sugar, such as diluted skimmed milk, buttermilk or casein milk. Mixtures may be gradually increased appropriate to the age and development of the patient, but the process should be slow, covering a period of several weeks.

When the diarrhea is caused by an excess of the putrefactive bacteria, the stools are brownish, foul, and alkaline. In feeding the protein must be kept low and the carbohydrate content increased. Beef juice, broth, albumen water and whey should not be

given. Any one of the cereal waters or gruels already mentioned, to which has been added milk sugar, or dextrimaltose, is a suitable beginning. In resuming milk the protein percentages in the milk should be low and very gradually increased.

The infectious type of summer diarrhea, known as ileocolitis, is distinguished by inflammation. It is frequently difficult to draw a sharp distinction between this and the fermentative. In both we have toxic substances resulting from bacterial growth, producing symptoms and in some cases pathological changes. In infectious diarrhea the bacteria principally concerned are the dysentery bacillus, the gas bacillus, colon bacillus, and the streptococcus. The stools in these cases are alkaline in reaction and show increasing frequency, with the presence of blood, mucus, and finally pus. Membrane may be present in the more severe cases.

The determination of the disturbing organism is not always possible. Streptococci may be discovered by the microscope, the gas bacillus by culture, and, according to Talbot, Baker has recently developed an intracutaneous test for the dysentery bacillus, which gives positive results in from six to eighteen hours. In cases of this type the complete withdrawal of food applies equally to breastfed infants, the usual diet being replaced by water, cereal decoctions or broth, as previously described. But the starvation period should not be too prolonged, particularly when accompanied by inanition, as the bacteria will tend to digest the protein found in the tissues, unless carbohydrate is quickly added to the diet.

For the purpose of dietary management, Talbot here divides the organisms into two general classes: first, dysenteric groups, and second, gas bacillus and allied organisms. In diarrheas caused by the first, or dysenteric group, and patient should be fed largely on carbohydrates. Lactose solution is probably the best form because of the development of lactic acid and should be given in a five to seven per cent. solution, either alone or with barley water.

As the acute symptoms subside, thickened cereal gruels, fresh beef juice, and broth thickened with meat fibre may be substituted for the weaker decoctions. In particular I would suggest the use of flour ball with either the cereal or broth diluent, or in the form of brown flour soup, using one or two teaspoonfuls with each feeding. Here again the return to any form of milk food should be begun with caution and abandoned at the first sign of relapse.

In diarrheas related to the second group of organisms—the gas and allied bacilli—the patient should be treated by feeding with a moderately high protein, the carbohydrates being kept low, and by introducing acid forming bacteria into the diet. Either skimmed milk, buttermilk or casein milk may be used, starting with a weak formula and increasing according to the progress of the patient, as indicated by the stools. Fat should be kept low. Convalescence will be slow, covering a period of from six to eight weeks or longer because of the tendency to relapse.

A bacteriological examination of the stools is not always possible. Clinically the question of suitable diet then becomes a matter of experiment, the feeding being reversed if the symptoms become worse.

In spite of frequent warnings as to the dangers of underfeeding in these trying and serious cases, I am confident that less danger can result from a careful dietetic management than from attempting to approach caloric requirements too early.

In many cases summer diarrheas are precipitated by the presence of some form of metabolic disturbance caused by an excessive amount of one or more of the food elements in the diet. As is well recognized an excess of fat or sugar rather than of protein is more likely to cause such disturbance. This condition must be considered in the return to diet following any diarrhea. The disturbing element must be kept low and introduced very slowly so as to overcome any previous intolerance.

Water Treatment in Diarrhea*

By JOHN D. DONNELLY, M. D.,
Philadelphia.

One of the complications of gastroenteritis when accompanied by vomiting and severe or prolonged diarrhea is dehydration. This is the result of rapid loss of water from the blood and tissues of the body, which in turn produces depletion of fluid in the circulation and tissues, consequently a concentration of the blood. Concentration of the blood diminishes its volume, increases its viscosity, diminishes its rate of flow, resulting in an accumulation of toxins and waste products, passive congestion of the kidney with oliguria, diminished oxidizing power of the

body cells, and favors a breaking down of body tissues.

Utheim (1) has shown that infants suffering from various diseases, with the exception of exudative diathesis and nephritis, exhibit no great change in their blood concentration. On the other hand, infants with vomiting and acute diarrhea have a high percentage of protein in their blood, the result of blood concentration.

Dehydration in infants, aside from evidences of loss of weight, presents certain definite signs. The fontanel is sunken, the skin takes on an ashy hue, which at times may be putty color, its turgor is lost,

*Read before the Philadelphia County Medical Society, May 11, 1921.

when folded or wrinkled it tends more or less to remain so, its elasticity is gone, the eyeballs recede, and oliguria is present. This state of dehydration calls for immediate replenishment of water in the infant's body. In the absence of vomiting and if the dehydration is only slight or beginning water by mouth usually suffices. When the infant will take water from a bottle or off a spoon, four to ten ounces daily (according to age) between feedings will maintain the water balance. If this method is not practical, water introduced by a nasal tube into the esophagus offers advantages in that it is painless and devoid of danger or of unpleasant after-effects, with the possible exception that irritation of the nares and nasopharynx may occur after the repeated use of the nasal tube. This can largely be obviated by the instillation of liquid petrolatum into the nose before the introduction of the tube and the use of a lubricant with a consistency sufficient to prevent it being easily wiped off the tube by the passage through the nose. White petrolatum serves this purpose admirably. After the tube has been passed into the esophagus, if its free end or the funnel attached to it is held under water, the absence of air bubbles makes certain that the tube has not been passed into the trachea.

When dehydration is definite or extreme, or in the presence of severe or prolonged diarrhea and vomiting, recourse must be had to means other than by way of the mouth for introducing fluid into the infant. Four routes are offered; by rectum (enteroclysis), subcutaneously (hypodermoclysis), intravenously, and intraperitoneally. We have never been able to utilize the rectal route with the degree of success which is apparently obtained by others. Rectal intolerance is usually established so early that the rectal injections become not only useless but actually harmful by setting up local irritation and reflexes which further stimulate bowel evacuations.

Hypodermoclysis of normal sterile saline solution may be used in threatened dehydration or in those cases where dehydration is only slight. Two to five per cent. dextrose (glucose) and sodium bicarbonate solutions may be used, but as their chief value lies in the water content of these solutions we rarely use them. We prefer the saline, as it is the most easily prepared and sterilized and, unlike the sodium bicarbonate, it does not have the attendant risk of producing sloughs. Saline when sterile is safe. However, hypodermoclysis is undoubtedly a painful procedure and the amounts which can be injected into small infants fall short of the needs of the average case of moderate or severe dehydration. Only about one hundred c.c. of saline can be administered at a time without causing discomfort to the infant. Larger amounts or multiple injections make the infant restless and irritable—the two things to be avoided in weak and dehydrated infants. In combating dehydration this method necessitates multiple punctures with their attending risk of suppuration, and therefore is not a method applicable for continuous use over seventy-two hours.

Intravenous administration of fluid has obvious advantages. We have used sterile solutions of normal saline, five per cent. glucose, three per cent.

sodium bicarbonate, and a glucose acacia solution, made up of glucose five grams, acacia ten grams, and normal saline, q. s. one hundred c. c. The practical difficulties of entering the infant's veins and the danger of the introduction of large amounts of fluid by the longitudinal sinus, have made us reserve this method for the treatment of marked dehydration cases only, where the call for replenishment of the depleted vascular system is an urgent one. When we use this method, the hair is shaved closely off the scalp covering the anterior fontanel and for an inch beyond. The injection into the longitudinal sinus which lies from three to five mm. beneath the scalp is made under the strictest surgical aseptic technic. The injection is made slowly, permitting the sterile fluid to enter by gravity at the rate of three or four c.c. a minute and at a temperature of 110° F. At the first sign of discomfort or marked change in the pulse or respiratory rate the needle is withdrawn, pressure made with sterile cotton over the puncture wound until all oozing has stopped, then it is cleansed with tincture of iodine and alcohol and a sterile cotton and collodion dressing applied. We have made numerous injections by this method and have not experienced any complications nor serious after-effects; on the contrary, many of our results have been most striking in their beneficial effects. The only contraindications to this method are the various forms of infectious dermatitis, particularly if the scalp is involved.

The use of the intraperitoneal route for the introduction of fluid is a comparatively recent therapeutic measure. In spite of the favorable reports of its use, it was not until we had satisfied ourselves on the cadaver that the penetration of the flaccid intestinal wall by the needle was really difficult to accomplish, were we willing to make use of this method. We have avoided the intraperitoneal injections in all cases where there was any abdominal distention, as the possibility of penetrating the intestinal wall under such circumstances cannot be denied. We carried out a series of experiments on guineapigs, employing various sterile solutions for intraperitoneal injections and found them to be without any toxic or local irritant action, when employed in proper amounts and in isotonic solutions. All fluids injected into body cavities and tissues for the purpose of immediate absorption must be isotonic and made of chemically pure substances. Otherwise, in many instances, abdominal distention, local discomfort, and signs of peritoneal irritation will follow intraperitoneal injections.

Reassured that these injections were devoid of serious risk we began our injections in the dehydrated infants and young children. Our technic is as follows: After excluding abdominal distention and the possible presence of an overdistended bladder the infant's arms and legs are restricted while in the recumbent position. The injection is made through the median line just below the umbilicus. The skin about this area is sterilized by the ordinary surgical method of preparation, tincture of iodine and alcohol. The skin and subcutaneous tissues are picked up between the thumb and the index finger of the left hand. A moderately large

(eighteen gauge), short beveled needle about two inches long, connected with a container by a rubber tube, is held in the right hand and inserted with a quick thrust, pointing upward and at an oblique angle, through the abdominal wall into the peritoneal cavity. The right thumb may be held on the needle about three quarters of an inch from the point so as to prevent too deep penetration. The sterile normal saline solution is then run in slowly by gravity at a temperature of 105° to 110° F. and continued until the abdomen is slightly distended. The needle is then removed and the puncture wound covered with a sterile dressing. Usually one to two hundred c. c. may be given to young infants, larger amounts to older babies. Any evidence of shock calls for immediate withdrawal of the needle and appropriate stimulation. The fluid should not be introduced too rapidly nor in too large quantities so as to avoid possible embarrassment to the diaphragm and heart. The whole procedure must be done under the strictest surgical aseptic technic.

During the past year we have used normal saline routinely in our intraperitoneal injections with gratifying success. A hypertonic solution of glucose (ten to sixteen per cent.) given intravenously after the intraperitoneal injection causes quicker absorption of the saline solution from the peritoneal cavity and urine excretion increases earlier than otherwise. Normal saline solution is absorbed comparatively rapidly, from the peritoneum. Postmortem examinations on infants who had received in-

traperitoneal injections from a few hours before death to weeks previously failed to show any evidences of injury or infection of the peritoneum or abdominal viscera.

The advantages of the intraperitoneal method of administering fluid to the dehydrated infant are those which were first pointed out in this country by Blackfan and Maxcy (2). They are: 1. Administration of large amounts of fluid at one time. 2. The fluid is quickly absorbed. 3. The method is a simple procedure, it is practical, and permits of repeated injections at frequent intervals with minimum risk to life.

As the circulation is replenished with fluid, by whatever method, the dehydration disappears, provided the excess loss by way of the bowel has been lessened by controlling the diarrhea, the infant's general appearance becomes better, the fontanel more full, pallor disappears, there are evidences of better circulation, both general and peripheral, toxicity is lessened, the oliguria disappears, and the whole picture is that of renewed and strengthened vitality. By this means we help tide over the necessary period for readjusting the infant's feeding and gastrointestinal tract.

The General and Dietetic Treatment of Eczema*

By J. P. CROZER GRIFFITH, M. D.,
Philadelphia,

Professor of Pediatrics in the University of Pennsylvania.

Before undertaking a discussion of the constitutional and dietetic treatment of eczema in early life, a brief consideration must be given to the etiology of the disease; since treatment must necessarily be directed, at least in part, against the cause. In some instances this is apparently purely local. The skin of the infant is by nature sensitive and easily irritated, and it is readily understandable that such influences as continued moisture from a wet diaper, lack of cleanliness and dryness in the folds of the skin, as, for instance, about the neck, chronic discharges from the nose or ears, excessive perspiration, exposure to cold winds, the presence of pediculi on the scalp, the employment of an excess of soap and water, and the like, may start a cutaneous irritation which may easily develop into an eczema. Even with these prominent local causes, apparently sufficient in themselves to account for the disease in many cases, there would seem to be acting in most instances some more distant factor; otherwise, common though it is, eczema would develop in every infant or child exposed to

the unfavorable influences mentioned. Among these more distant factors, which we may call constitutional as a matter of convenience, are to be mentioned individual predisposition, inheritance, the exudative diathesis, overfeeding, other errors in diet, digestive disorders, disturbance of the urinary secretion, and impairment of metabolic processes. Limitations of space prevent a discussion in detail of the possible action of each of these factors, but I may be permitted to refer to some of those oftenest active in early life, since they bear so closely upon the treatment to be employed.

The exudative diathesis, as it was first called by Czerny, is a prominent predisposing factor, often combined with evidences of lymphatism. The children suffering from this condition show a tendency to inflammation of the skin and mucous membranes. Many of the instances formerly called scrofulous are properly to be included here, these consisting merely of cases of localized tuberculous processes occurring in exudative subjects. There is in the exudative diathesis a special tendency to the development of eczema in infancy, replaced often later by a disposition to asthma, recurrent bronchitis,

*Part of a Symposium read at a joint meeting of the Philadelphia Pediatric Society and the Philadelphia Pathological Society, March 8, 1921.

urticaria, and the like. It would be incorrect, I believe, to attribute all these to some so-called anaphylactic response. There exists the modifying basic tendency which we may call exudative. This tendency can be cured only by the passing of time, but the exciting agent which produces an attack of eczema should be sought for and removed. The causes of this nature are chiefly dietetic, and the treatment will be discussed presently.

Overfeeding is a prominent cause of eczema, even when this does not result in any evident digestive disturbance. It is a noteworthy fact that the healthy appearing, or often somewhat anemic, very fat, breastfed infants seem especially disposed to eczema. The disorder is very much less common in wasted babies. Gastrointestinal disturbances also constitute a prominent cause of the disease. It is frequently observed that an infant who has nearly or quite recovered from a more or less persistent eczema relapses readily, with the appearance of coating of the tongue, vomiting, or other sign of indigestion. Constipation, too, is an important factor in this category.

But apart from distinctly digestive disturbance, the specific influence of diet is remarkably evident in many instances. Often there appears diminished tolerance for sugar, especially maltose, and an alimentary glycosuria is readily produced. In one case under my care eczema was completely relieved by using lactose instead of the pure maltose which had been employed in the milk mixture. Other carbohydrates, such as the starches, may be the agent. Thus, in one instance the mere change from an oatmeal water diluent to one of barley water was sufficient to cure the disease. Frequently an excess of fat in the food is clearly the cause. In a recent case the reduction of the percentage of fat from two and seven tenths to two, was followed in twenty-four hours by remarkable improvement. The mineral matter of the diet has been accused by Finkelstein and others. Whether the protein can be an active agent is uncertain, yet it has at least been shown by Schloss that infants with eczema will in many instances exhibit a cutaneous reaction to certain proteins. With this statement other observers are in accord. White believed that the majority of cases of eczema will react to a cutaneous food test; Blackfan found a cutaneous reaction in twenty-two of twenty-seven cases of the disease, and O'Keefe in a recent article observed a positive protein reaction in forty-one per cent. of seventy cases studied, all the patients being under four years of age.

It is evident, therefore, that whereas food is a prominent factor, the active ingredient of this in the production of the disease must vary with the case. In this matter a most careful study of the diet is necessary in each instance. It is noteworthy that infants with eczema are prone to recover completely when the first year is passed, and a more general diet is commenced. We cannot be certain that this is due to the dietetic changes, but it is at least suggestive, and indicates that a diet solely or largely of milk may be the etiological factor in some instances.

With these facts in mind we are prepared, as far as we can be in view of our lack of exact knowl-

edge, to undertake the constitutional treatment of an infant with eczema. This may be divided into eliminative, dietetic, and medicinal. It was pointed out to me years ago by an eminent dermatologist of this city, who in turn had received the hint from an eminent obstetrician with large practical experience among women and children, that excellent results were often obtained in eczema by giving a purgative every five days. Calomel was the drug used, followed by magnesia, if the calomel alone failed to purge. I do not know that calomel is any better than any other purgative for the purpose, but certainly purgation brought about in some way has been very successful in my experience. Of course between these cycles of purgation attention must be given to the satisfactory daily evacuation of the bowels. For this purpose we do not want local measures, such as enemata and suppositories, but laxatives in small doses given by the mouth. Of course, too, reliance is not to be placed on the purgative treatment alone, but appropriate dietetic measures are to be sought for as well. First of all, an excess of food is to be avoided. The fat, rolypoly baby may be a joy to its mother, but is no healthier than others with only normal weight. Certainly if eczema develops, the amount of food must be decidedly reduced, whether the fat baby is breastfed or bottlefed. If it is not an instance of overfeeding in the total quantity of all the ingredients, then a careful experimental study must be made of the influence of each of the different food elements. We may advise a diminution in the amount of fat, and after this, if not successful, in the amount of sugar. In view of the tendency to cutaneous reactions seen in some of the cases, a reduction of some of the animal or vegetable protein of the food should be tried, after cutaneous tests have been employed to determine which protein may reasonably be suspected. Finally, in the case of infants of an age to permit it, the total amount of milk given may well be lessened, and the caloric value of the diet made up by the addition of starchy substances—always provided that starch has not been proved to be a factor in the production of the disease in such a patient. Broths are not always well borne. Perhaps this is in the cases where an excess of mineral matter is the active agent.

Before coming to any positive conclusion, however, regarding the specific influence of some element of the infant's diet, the question of the state of the general nutrition must not be forgotten. Thus, for instance, Plantenga in an article discussing the action of the butter flour mixture recommended by Czerny and Kleinschmidt, pointed out the fact that whereas some infants with a tendency to eczema were always made worse when this diet, rich in fat and carbohydrate, was given, others decidedly improved, on account of the benefit which accrued to their general nutritional state. This appeared to indicate that in the first instance the eczema was purely dietetic, while in the second it was more of a general constitutional nature.

In subjects past the first year of life, a similar study of the effect of diet must be carried out. Certain articles of diet appear to bring on eczema in certain children, without there being of necessity

any evident gastrointestinal disturbance produced. In general eggs are to be viewed with suspicion, and the milk may be tentatively much reduced in amount, or even for a time omitted from the dietary. Sometimes it is an excess of starch in the food which appears to be the cause. Only trial can determine which element is to blame.

In the way of medicinal treatment our armamentarium is limited. For infants who are experiencing loss of sleep and consequent loss of health, the result of the persistent itching, phenacetin or the bromides may be of benefit. For those with anemia iron is often useful, and especially cod liver oil. For the eczema attending chronic nasal or aural dis-

charge, and occurring in subjects of the exudative diathesis, this latter remedy is especially indicated. Bicarbonate of soda or other alkali in full dose is recommended for those subjects in whom eczema is associated, in themselves or in their parents, with asthma, recurrent vomiting, and recurrent bronchitis. Arsenic, formerly much in vogue, is now largely discredited. It has seemed to me, however, occasionally of benefit in chronic cases. Finally, the employment of purgatives, especially salines, to which reference has already been made, is to be regarded as one of the most important elements of internal medication.

1810 SPRUCE STREET.

The Management of Babies and Children Suffering from Summer Diarrhea*

By A. GRAEME MITCHELL, M. D.,
Philadelphia.

At this season of the year the consideration of summer diarrhea is timely. Often as the subject is discussed it never lacks interest, as the prevalence of the condition continues to be of the most serious consequence to the baby. In the first year of life the diarrheal diseases still cause about one quarter of the deaths. Furthermore, methods of treatment differ even among those who have given the matter most thought. We are justified in speaking of the diarrheal diseases provided we recognize that diarrhea is only a symptom of a number of different conditions.

What constitutes diarrhea? The statement of the mother is often unreliable in this respect. Her idea as to the number and character of the bowel movements that the baby should have may be incorrect. We may accept her statement as to the number but the character must be ascertained from personal inspection. In general it may be said that a baby should not have more than three stools a day.

Before entering upon a discussion of the management of summer diarrhea one must give some thought to etiology. The influence of certain factors is undisputed.

Age.—The larger percentage of cases of summer diarrhea occurs under two years of age. Babies at this age are more exclusively milk fed than older children, and they are also, as unstable and susceptible organisms, more easily influenced by infection and heat.

Time of year.—Summer is the season of most frequent occurrence of diarrheal disorders. The two influencing factors at this time are heat and infected milk. The prevalence of summer diarrhea seems to be in direct ratio to heat. Heat favors the growth of microorganisms in milk, and also causes lowered resistance on the part of the baby—a lowered digestive ability.

Type of feeding.—That bottlefed babies are more susceptible to diarrheal disorders than breastfed babies in the ratio of five to one is axiomatic. This would lay almost the entire blame for causation upon dirty and infected milk. One must remember that harmful bacteria may be introduced into the gastrointestinal tract in other ways than in milk. It is probable also that certain bacteria may be present in the digestive canal and not become pathogenic until an opportunity is offered for their growth by lowered resistance in the host. Just as the pneumococcus may be present in the mouth and not be pathogenic, so the dysentery bacillus may be a quiescent inhabitant of the normal gastrointestinal tract until a favorable field offers occasion for its proliferation and the development of its toxic properties.

State of health.—This has an influence, not only upon the susceptibility of the individual to infection, but also upon the severity and end result.

Poverty, uncleanliness and overcrowding.—These conditions increase the number of cases of summer diarrhea in various obvious ways.

Etiologically the diarrheal diseases must be divided into some classification. Thus we have mechanical diarrhea due to the ingestion of unripe fruit or vegetable matter difficult of digestion; nervous diarrhea due to the action of extremes of heat or cold, excitement or fatigue; metabolic diarrhea such as occurs in the course of an acute infection, or the eliminative diarrhea of uremia; infectious diarrhea due to the action of bacteria or their toxins; the diarrhea of indigestion due to too much food, or to the improper balance of food ingredients. Whatever the initial cause of diarrhea all types may eventually become infectious in nature. For example, a diarrhea beginning as the result of an excess of sugar in the food may be continued because of the change in intestinal flora and the proliferation of acid forming bacteria.

*Read before the West Philadelphia Medical Association, April, 1921.

In Finkelstein's classification of nutritional disturbance one finds the term alimentary intoxication. The symptoms which he describes as occurring in this condition (disturbances of consciousness, change in respiration, glycosuria, fever, diarrhea, collapse, albuminuria, disturbance in the weight curve and leucocytosis) are those which are present in the severe forms of summer diarrhea. It is difficult to accept Finkelstein's view that these symptoms are due alone to the chemical injury of food and that bacteria have nothing to do with the production of intoxication. Even admitting that various symptoms may be produced by giving food to a child whose tolerance for such food is diminished, it has not been proved that bacteria have nothing to do with the causation of the symptoms. The end results, such as acidosis, may be chemical in nature, but it cannot be denied that in gastroenteritis, not only are certain harmful bacteria often found in large numbers, but that the patient's improvement is coincident with the disappearance of these organisms and the change to a normal flora.

A satisfactory classification of the diarrheal disorders, from the point of view of treatment, is a rough division into three groups as follows: mechanical, when the intestinal mucosa is irritated by raw fruit or uncooked vegetable matter; fermentative, when abnormal fermentation of the food in the digestive canal takes place, due to the action of bacteria already present or introduced from without; infectious, when the bacteria instead of being saprophytes are true parasites and attack the intestinal mucosa itself, often causing serious lesions. It is, of course, recognized that mechanical diarrhea may merge into fermentative, and fermentative may merge into infectious diarrhea. The usefulness of a classification such as is given above will be especially apparent when the management of diet is considered.

It will be easier to proceed if the therapeutic measures are dealt with in their application to different types and grades of severity of gastroenteritis, and later the treatment of special symptoms and the diet outlined.

Purgation.—The question often arises as to whether a purgative should be given. It is undoubtedly a mistake to purge in every case of gastroenteritis. When the digestive canal has already rid itself of offending material, when the intestinal discharges are frequent and watery and dehydration is present, purgation may be harmful as well as unnecessary. If, however, fever is high and the stools contain undigested food and much mucus, an initial purge is indicated. Castor oil is usually the best, especially in view of its constipating aftereffect. If vomiting is marked, oil may not be retained and calomel may be given and followed by a saline.

Gastric and colonic lavage.—These may be good therapeutic measures in the beginning of an attack of summer diarrhea. If vomiting is a noticeable feature of the case one or two washings of the stomach with normal saline solution, or five per cent. sodium bicarbonate solution, are helpful. Colonic lavage may be done several times when the temperature is high and there is considerable offending material in the bowel. It is rarely necessary to

continue very long with colonic irrigation and it should be done cautiously, if at all, when there is blood in the stool.

Medication.—Drugs are to be used for several purposes in gastroenteritis; for purgation; to check diarrhea; for stimulation; to combat acidosis; as intestinal antiseptics; for the relief of symptoms such, for example, as pain and restlessness. The emptying of the intestinal tract by purgative drugs has already been spoken of. In giving drugs to combat diarrhea one should remember that frequent bowel movements, certainly in the beginning of a gastrointestinal upset, act as an eliminative measure. It has been pointed out that when there is fever and the digestive canal contains offending material, diarrhea is to be encouraged, but that it may continue and cease to be beneficial. Frequent watery stools lead to a fluid loss which eventuates in dehydration of the infant. When dehydration is present there is no fever, the temperature, on the contrary, often being subnormal; distention has disappeared; anything taken by mouth stimulates peristalsis and a stool results. This is the time to give such remedies as bismuth (subgallate or subcarbonate) in large doses, and if these drugs do not have the desired effect, one should not hesitate to use opium in sufficiently large doses to diminish the bowel movements to a reasonable number. For stimulation, digitalis, strychnine, atropine, caffeine, and camphor are indicated at times. The use of alcohol is often of value. It may be retained when other fluids are not, and its calories are an aid. Intestinal antiseptics are probably useless in the doses in which they may be given. Abdominal pain and restlessness are best combated by measures other than drugs. The restlessness due to toxemia is relieved when the toxemia is overcome. Occasionally quiet is so urgently needed that a small dose of morphine should be given hypodermically.

General hygienic measures.—These are of great importance and the mother should always be instructed in them. The baby's surroundings, fresh air, avoidance of chilling or of too heavy clothing which prevents a proper radiation of heat, bathing and sponging, are matters which should be under the supervision of the physician just as much as the administration of drugs or the prescribing of the diet.

So far the treatment has been comparatively simple. Not so, however, with the more serious cases of summer diarrhea—those that really tax the physician's skill. One may well ask the question, What is the cause of death in these severe cases? When one sees a child prostrated and toxic; the eyes, fontanel and abdomen sunken; the temperature excessively elevated or subnormal; the skin lax and easily lifted between the fingers; the mental condition one of irritability or coma; the urine scanty and containing albumin, casts and often sugar; the respiration infrequent and deep—from what is that child suffering? He is ill and he will die from a combination of two conditions—dehydration and acidosis. If one is to save such a child the most vigorous methods must be adopted. Purgation, irrigation, drugs, diet will not be of avail in such an extremity.

Intraperitoneal administration of fluid.—When dehydration exists, or dehydration and acidosis exist together, fluid is urgently indicated. Unfortunately fluid given by mouth or introduced by rectum will not always be retained; vomiting and diarrhea cause its expulsion before it can be absorbed. Moreover, if absorption does take place it is too slow for the immediate needs of the child. Fluid may be given by hypodermoclysis or intravenously, but the procedure of choice is the intraperitoneal route. More fluid may be given in this manner at more frequent intervals, and with less distress to the patient, than by any other method. The only contraindication to the intraperitoneal injection of fluid is abdominal distention. Normal saline is the solution employed. The same type of needle and apparatus which would be used for hypodermoclysis is required. Having first ascertained that the bladder is empty the skin of the abdomen midway between the symphysis pubis and the umbilicus is lifted with the fingers of one hand, and the other hand plunges the needle (with saline solution flowing from it) through the abdominal wall. The fluid is allowed to flow until distention of the abdomen occurs, which may be after 150 or not until 300 c.c. have been introduced. The intraperitoneal injections may be given many times and repeated within eight hours if necessary.

If acidosis is present large doses of alkalis may be given by mouth or rectum. Intravenous injections of sodium bicarbonate and glucose have their place in this connection. It should be emphasized that if dehydration can be prevented or successfully combated acidosis will not occur.

Diet.—The most important part of the management of a case of summer diarrhea is the giving of a proper diet. Thus far the etiology of the disease or the cause of symptoms have not concerned us. That is to say, whatever the reason for the vomiting, the diarrhea, the dehydration or the acidosis, they must be prevented if possible and treated if present. With the feeding, however, it is different. Not all patients with gastroenteritis can be fed in the same manner. Before following any method of feeding in these cases one must decide whether to adopt the bacteriological or the chemical classification of etiology. The bacteriological theory of causation seems to be the more satisfactory to adhere to when planning the diet. Not that every condition in which diarrhea is a symptom is necessarily due in the beginning to the action of bacteria, but many diarrheal diseases are so caused, and there is no gainsaying the fact that a change in the type of the intestinal flora is coincident with improvement in the symptoms. Such change in intestinal flora can be brought about by diet.

If it is considered that the condition known as gastroenteritis is due to bacterial action, it is necessary to distinguish between two main types—fermentative and infectious. In fermentative diarrhea the bacteria in the intestinal tract cause fermentation of the food with the formation of products which irritate the intestinal mucosa and cause diarrhea. In infectious diarrhea the bacteria not only act on the food contents of the digestive canal, but the mucosa itself is attacked. In fermentative diar-

rhea the bacteria at work are saprophytes, in infectious diarrhea they are true parasites. The bacteria which inhabit the intestinal tract in health and disease are of two groups—acid forming and putrefactive (or protein splitting). The acid forming bacteria thrive upon carbohydrates and the putrefactive thrive upon protein. If one can determine which group is causative in a given case the indications in planning the diet are clear. If the acid forming group is at fault, then the patient must be fed food high in protein and low in carbohydrate; if the putrefactive group is the trouble maker, then the food must be high in carbohydrate and low in protein. Such a diet would discourage the growth of the causative group, but encourage the growth of the antagonistic group.

In the majority of cases of summer diarrhea of the fermentative type there is an active proliferation of the acid forming bacteria in the intestinal tract. These are the cases where the intestinal discharges are frequent, green, and so highly acid (due to the action of formic, acetic and butyric acids) that the buttocks are scalded. Litmus papers shows the reaction, and it should be introduced into the rectum by a glass rod or thermometer so that the acid reaction of urine mixed with the stool will not confuse the result. In fermentative diarrhea due to acid forming bacteria the patient should be fed as follows:

In the milder cases all that is necessary is to remove sugar and boil the mixture. In the severer cases a preliminary period of starvation is to be carried out unless the intestinal tract has already rid itself of harmful material. Twelve hours is usually enough and during this time fluid, preferably as water or weak tea sweetened with saccharine, should be freely administered. After the starvation period there are several choices of food, all of which have a low carbohydrate content and a comparatively high protein content. Fat should be kept low, because in all intestinal derangements the digestion of this food element is interfered with. Boiled skimmed milk answers these requirements and it should be fed in dilutions and amounts that depend on the age and weight of the child, as well as the severity of the infection. Later, as improvement occurs, fat and sugar may be cautiously added to the food. Finkelstein's albumin milk would be indicated in this type of diarrhea because of its low carbohydrate and high protein content. Powdered casein or calcium caseinate may be added to the skimmed milk mixture to reinforce the protein. Milk fermented by the action of lactic acid bacilli has been used in this type of diarrhea with good clinical results. If used, lactic acid milk should be comparatively fat free, at first, and no sugar or other carbohydrate added.

There is a protein form of fermentative diarrhea in which, instead of green acid stools, the patient has brown, foul, alkaline stools. Under the conditions the indication is clear to give low protein and fairly high carbohydrate, such, for example, as weak milk mixtures with carbohydrate added as lactose and starch.

When the intestinal discharges contain blood and pus the patient is suffering from infectious diar-

rhea. From the macroscopic appearance of the stool it is impossible to tell what organisms are at fault. Bacteria belonging to the dysentery group are not infrequently found, but the gas bacillus may be present. It is important to know which of these organisms is causative as the management of the diet is radically different in the two types. The reaction of the stool is again a help because the dysentery bacillus, being a protein splitter, gives an alkaline reaction to the stool, whereas the gas bacillus is an acid former. However, the gas bacillus should be searched for. If careful bacteriological examination of the stool is not possible, a very simple clinical test will suffice. This is performed as follows:

To a test tube half full of milk add a peasized portion of the stool and shake well. Boil for three minutes. This will kill all the usual organisms in the stool with the exception of the gas bacillus which is a spore former. Set the test tube aside in a warm place, preferably an incubator, for twelve to twenty-four hours. At the end of this time the milk will be shot full of holes (gas bubbles) if the gas bacillus has been present in the stool. In a given case of infectious diarrhea, if the test for gas bacillus is negative the patient may be assumed to be infected with the dysentery group.

The dysentery bacillus thrives and produces its toxin when given protein to grow upon. The feeding consists of nothing but barley (or other cereal water) for twenty-four hours. The next twenty-four hours eight per cent. of lactose may be added to the cereal water. Not until the third day is a

small amount of skimmed milk added to the cereal water and lactose solution. At times, especially when the patient is seen late in the course of the disease, food is so urgently needed that the preliminary starvation period cannot be carried out.

If the gas bacillus is found the feeding may be the same as that which is recommended for fermentative diarrhea due to the acid forming group of bacteria. However, lactic acid milk is a specific for gas bacillus infection and should be the feeding of choice.

Summary.—Children and babies suffering from gastroenteritis cannot be treated routinely. One must consider in the management of an individual case the condition of the patient, the type of diarrhea, and the severity of the disturbance. If blood and pus are absent in the stools the fermentative type of diarrhea is the probable form present. If the stools contain blood and pus the patient has the infectious form of diarrhea, and the test for gas bacillus should be made. In fermentative diarrhea there are two subdivisions—the common form, due to the activity of the acid forming group of bacteria, and the uncommon form, due to the proliferation of the protein splitting organisms. Each of the different varieties of diarrhea are quite easily recognized clinically, and each has a definite dietary indication. Purgation, irrigation, and lavage are to be used only as required in the individual case. Dehydration and acidosis are conditions to be prevented if possible; if present they demand urgent treatment.

The Treatment of Nutritional Disorders in Artificially Fed Infants*

By CHARLES HERRMAN, M.D.,
New York.

Although a discussion of rickets and scurvy would properly come within the scope of the title of this address, in order to keep within the space limit I shall omit these two diseases. I shall not attempt to discuss the subject in detail, but simply emphasize certain principles which should guide us in the treatment of the nutritional disorders of artificially fed infants. I believe the term nutritional disorders is preferable to digestive disorders, because the latter focuses the attention on the gastrointestinal tract, to the exclusion of many other parts of the body which are also affected.

Classification.—On account of our incomplete knowledge, a perfectly satisfactory classification of these disorders is extremely difficult. In this country, those of Holt and of Morse and Talbot are perhaps best known. Holt describes as separate entities, acute inanition, malnutrition, marasmus, acute and chronic gastritis, acute and chronic gastric indigestion, acute and chronic intestinal indigestion, acute and chronic ileocolitis, and cholera infantum.

This subdivision into a large number of groups is rather complicated. As a rule more than one segment of the digestive tract is affected and it is not always easy to determine from the symptoms just which portion is involved. The presence of vomiting is not characteristic of any one type, and we cannot always determine the character of the pathological changes in the bowels, from an examination of the stools. Even in the fatal cases of marasmus the pathological changes may be very slight. Morse and Talbot divide the cases into simple indigestion, indigestion associated with fermentation, and infectious diarrhea. They admit that it is often extremely difficult to differentiate between them, that they often merge into each other, and that it is largely a difference of degree or severity. As they state, cholera infantum has never been shown to be associated with a specific microorganism, and it is not even certain that it is of bacterial origin. It may simply represent the result of some profound disturbance of metabolism.

Etiology.—I believe that the original division of Czerny and Keller is simple and satisfactory: 1.

*Read before the Bronx County Medical Society, May 18, 1921.

Disturbances due to the food. 2. Those due to infections. 3. Those due to constitutional peculiarities of the patient. In the first group, the disturbances may be due to the quantity or the quality of the milk, or to one of its constituents. The second group comprises those associated with bacterial infections. The third represents an important group. Although it is recognized in a general way that some individuals are congenitally inferior, the laity especially do not appreciate the bearing of this fact on the individual infant. Mrs. Smith does not understand why her infant does not thrive when artificially fed, while Mrs. Jones's does beautifully. There must be something wrong with the formula.

There can be no doubt that some infants are below par when born. To mention only two well recognized types, there are the exudative and the spasmophilic or the hypertonic infant, which my colleague, Dr. Haas, has described so fully and studied so carefully. A large number of the difficult feeding cases belong to these groups.

I believe it will be better for the present not to draw the lines too sharply between the various forms of disturbance. To a great extent they represent different degrees of severity, and often merge into each other. Bearing this in mind we may conveniently divide the cases into four groups; these do not represent disease but conditions with which certain manifestations are associated.

1. The hypotrophic infant which is retarded in its development, which does not gain properly in weight, although no definite digestive disturbances are present.

2. The atrophic infant which represents an extreme grade of the preceding. This is a severe type of nutritional disturbance, with distinct retardation in development. Such infants are pale, the tissues lack tone, so that when a fold of skin and subcutaneous tissue is lifted, it stays put, and their temperature is unstable.

3. Infants with indigestion—that is, those who vomit, have abnormal stools, or both.

4. Those infants with symptoms of toxicosis. Beside fever and loss in weight, these infants present a characteristic change in the breathing, hyperpnea, and disturbances of the sensorium.

In the treatment of an infant with a nutritional disturbance, a complete history may be of the utmost importance. In those infants who are constitutionally inferior, the family history may show some members who have had eczema, asthma, or are of neuropathic tendency. It is important to know whether the baby was born prematurely and whether there is any constitutional disease in the parents, more especially syphilis. The weight at birth, and at various times since birth should be ascertained, also the exact kind of feeding since birth, whether there has been any disturbance previously, vomiting, abnormal stools, and whether it sleeps well. It is also important to note the child's disposition, facial expression, the condition of the sensorium, and the tone of the tissues.

Early treatment.—The sooner a patient is treated the better. There is too great a tendency among some to belittle the importance of nutritional disturbances, and frequently to attribute them to teeth-

ing. In this way valuable time is lost, for a mild disturbance is usually easily controlled, whereas a severe one may be impossible to treat successfully, even with the best surroundings and the most expert advice.

Attention to detail.—This is of prime importance, instructions should be written clearly, an anxious mother frequently forgets. Directions should be carried out, the food should be prepared and given as prescribed. In the severer cases, when the circumstances permit, it is preferable to have the patient in charge of a trained nurse. In a few cases in which relatives and friends interfere with the proper treatment at home, institutional care may be desirable. If there is a maternity ward attached to the hospital, the possibility of procuring breast milk is an additional advantage.

Contrast feeding.—As the choice of a new food is often in the nature of an experiment, the principle of contrast feeding is rational. The infant is placed on a food which is widely different from the one on which it did not thrive; for example, if it was doing badly on a high fat mixture, skimmed milk would be employed; if it was not making progress on a mixture containing a large percentage of carbohydrates, protein milk would be indicated.

As an underlying principle, after an acute disturbance, we begin with a small quantity of an easily digestible food, and increase the amount and strength gradually, noting the child's tolerance as manifested by an increase in weight and the absence of fever, vomiting, and abnormal stools. It is not unlike the guiding principle in the modern treatment of diabetes.

Prophylaxis.—As I have stated on a previous occasion, infant feeding is a song of many stanzas, but the refrain remains always the same, cow's milk is not woman's milk. A very large percentage of mothers, if properly encouraged and advised, can nurse their infants at least during the first few months. In 1909 and 1910, I followed up all the infants born in the maternity ward of Lebanon Hospital, and found that eighty per cent. nursed their babies entirely or partially for at least five months. Recently, by following practically every baby born in Minneapolis during a stated period, Sedgwick has demonstrated that ninety per cent. of all babies can be nursed at the breast. Infants should be kept cool during the summer months. Overheating is undoubtedly an important etiological factor in the causation of digestive disturbances in the summer. Water should be given regularly. The dehydration of the tissues, even if it is not the only factor in the causation of what we term acidosis, is certainly an important one. The milk should be of the very best quality and kept cool. Everything which comes in contact with the milk should be scrupulously clean.

TREATMENT.

Hypotrophic infants.—In those infants who are retarded in their development and do not gain in weight, the possibility of an underlying constitutional disease, more especially syphilis, should be borne in mind. Premature infants who do not thrive, usually require breast milk. If these factors

can be excluded, it should be ascertained whether the infant is receiving a sufficient amount of food. It is not advisable to give a milk mixture of less than one half strength—that is, half milk and half water, with the addition of sugar. The caloric requirements of a hypotrophic infant are greater than those of a normal infant—namely, from fifty-five to sixty calories a pound. In mild cases, the addition of dextrimaltose instead of cane or milk sugar may be sufficient to obtain a gain in weight. If the child is constipated, and the stools putty-like, a malt soup mixture will usually improve the character and the regularity of the stools. The proportions of the milk, flour, malt soup extract and water can be modified to meet the individual case, according to the age of the infant, and whether or not the bowels are constipated. For infants over six months cereals and zwieback may be added to the diet. A few may not gain in weight until fresh vegetable and fruit juices are added.

2. *Atrophic infants.*—These represent a more severe and advanced stage of the preceding group and are more difficult to handle. As their heat regulation is defective and they often have a subnormal temperature, they must be kept warm. Many of them, especially those under three months, require breast milk. After the danger period has been tided over, it may be possible to continue the improvement on a malt soup mixture. Such infants have a high caloric requirement per pound, and must therefore be given large quantities of food. It is in this group that the principle of contrast feeding sometimes finds its greatest usefulness.

3. *Indigestion.*—In cases of indigestion the indications are to remove the irritating and deleterious material from the gastrointestinal tract and to withhold food. The first is best accomplished by giving a dose of castor oil. If this is vomited, calomel may be substituted. If the vomiting persists, in

spite of the withdrawal of food, the stomach may be washed out. If the diarrhea continues after the irritating material has been entirely removed, small repeated doses of the camphorated tincture of opium are indicated. The infant is given water, barley water or tea, if possible in amount equal to the amount of milk which it is accustomed to take. If this cannot be given by mouth, it may be given by rectum, either by the Murphy drip method, or several ounces may be introduced three or four times a day. Food is withheld for twelve or at most twenty-four hours. In those cases in which the indigestion is associated with marked fermentation in the bowel, protein milk is given. In simple indigestion, I usually begin with a milk powder, preferably made from skimmed milk, of which there are now several on the market. Later the infant may be given skimmed milk and gradually brought back to diluted whole milk with dextrimaltose added.

4. *Toxicosis.*—Infants with manifestations of toxicosis are desperately ill, so that even with the best possible care the majority succumb. While the acute symptoms, hyperpnea, fever and disturbed sensorium, are present, food is withheld for twelve to twenty-four hours. The tissues must be supplied with large quantities of water. If this cannot be given by mouth or rectum, it can be given subcutaneously, intravenously or intraperitoneally. The last method has now been employed in a large number of hospitals, and has been shown to be effective, and without danger. After the acute symptoms have subsided, very small quantities of breast milk, one teaspoonful every hour or two, are given, and the amount is gradually increased, the infant being watched for any recurrence of symptoms. If the patients can be tided over the danger period, a small number may be saved, but the prognosis is always extremely grave.

76 WEST EIGHTY-SIXTH STREET.

Unemphasized Essentials in Infant Feeding*

By JESSE R. GERSTLEY, M. D.,

Chicago.

Probably one of the most important causes of dissension among pediatricists of the various schools is the significance attached to stool examination. In the diagnosis and therapy of infantile diarrheal disease a large number of skilled pediatricists are guided largely by the baby's diaper, and if this does not suffice, by the microscope. The presence of fat establishes a fat diarrhea, or undigested starch a starch diarrhea. Treatment then reduces or removes the offending element of food. While much success must attend this method, nevertheless another procedure may be a little more appropriate to the changing philosophy of the day.

This is distinctly the era of the baby. Pediatricists

*From the Northwestern University Medical School and the Michael Reese Sarah Morris Hospital for Children.

concern themselves more and more with their patient as a whole. The era of pathology is on the wane. To the interest in the entire child, the painstaking pathological anatomical diagnoses of the previous decade become of minor importance. To establish laborious minutiae of pathology is not as important to physician or parent as to succeed in developing a happy, smiling, and thriving child. So in the methods of treatment adopted by some pediatricists, definite clinical symptoms and even unquestionable pathological diagnoses are often disregarded in the larger interest of the patient's welfare. The index of the latter is the weight curve and not the stool.

Stool examination unquestionably tells of conditions in the gastrointestinal tract. Suppose we say,

however, that we are more deeply concerned with the whole baby than with the stomach and the intestines. Perhaps, if we disregard the gastrointestinal symptoms to some extent and devote our treatment to the weight curve—i. e., to the whole body—local symptoms will improve proportionately to the improvement in the general condition.

To be more specific. In a case of diarrhea of a

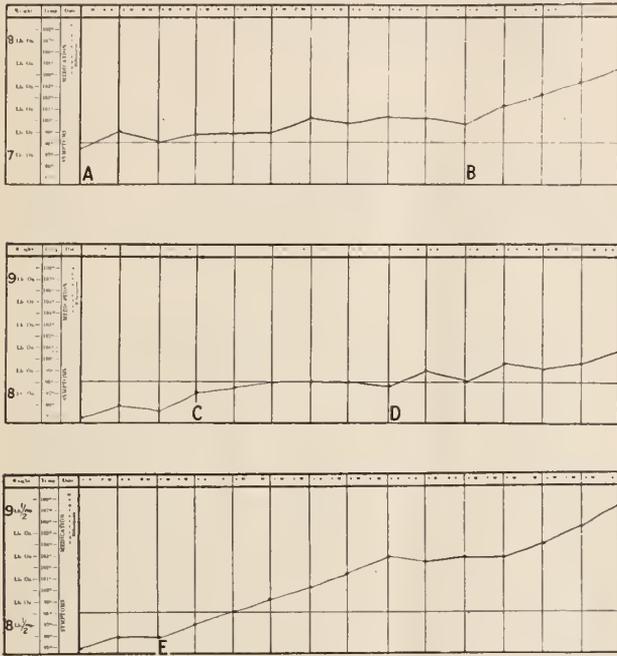

Chart I.—A, Child's feedings had been increased to albumen milk twenty-eight ounces with three per cent. dextrimaltose. B, Dextrimaltose five per cent. C, Daily total thirty-two ounces. D, Dextrimaltose seven per cent. E, Dextrimaltose nine per cent. In this case as the stools were normal throughout there could be little question as to the advisability of the increase.

fermentative or even an infectious nature two problems must always be borne in mind. First, what is the condition of the child's intestine? Logically, the food prescribed should be the most easily tolerated and assimilated. The second problem, What is the condition of this child's body? is more important. What is needed to increase resistance to this disease? How can we guide the needed nourishment through the intestinal wall?

Scientifically, upon an experimental basis, these problems may not have been answered. Clinically, however, the problem is fairly definitely settled. To carry on the daily work, to thrive, to keep up temperature, to furnish energy for metabolism, above all things to gain weight, the body needs carbohydrate. Even in a healthy child, the response of the weight curve to dietetic variations of carbohydrate is striking. Much more pronounced is the reaction of the infant suffering from malnutrition or decomposition. Here the presence or absence of carbohydrate determines life or death.

At once it would appear that the problem of therapy becomes complex. Carbohydrate fermentation in the intestinal tract produces irritating acids which cause severe diarrhea with resulting dehydration, prostration, loss of weight, and collapse. Carbohydrate is the fuel so badly needed by the starving cells of the body. To increase the amount

in the ordinary way is out of the question. Fermentation becoming wild and uncontrollable sweeps on to a fatal alimentary intoxication.

This problem, the dilemma of pediatricists for years, has at last been solved by albumen milk. Based upon the older philosophy of exclusive attention to the gastrointestinal tract albumen milk was devised with the idea of combating intestinal fermentation by reducing carbohydrate and whey. It serves this purpose well, but the loss in weight following its administration showed that it did not meet the larger demands of the baby's body.

Further studies showed that upon a diet of albumen milk the child's body to exist needed a minimum of three per cent. carbohydrate. Further work demonstrated that often five per cent. became necessary. But if no weight increase follows what then? Suppose fermentation stopped by albumen milk is activated again by the increasing carbohydrate. Here our new philosophy becomes useful—the intestine or the baby? Obviously the intestine suggests a decrease of carbohydrate. The body as evidenced by the stationary weight curve demands an increase. Thinking of the baby first, we consider an increase to seven per cent. and if no response even nine per cent. Perhaps if sufficient carbohydrate enters the body, in spite of some lost in the increased diarrhea, the improvement in the general nutrition may result in a corresponding improvement of the gastrointestinal tract. That this philosophy leads to success is evidenced by a large series of cases, but as yet the majority of the profession seem loath to adopt such radical teaching. It must be emphasized, however, that such methods can be employed only with albumen milk. This mixture with its high protein and low whey seems able to cope with a high carbohydrate

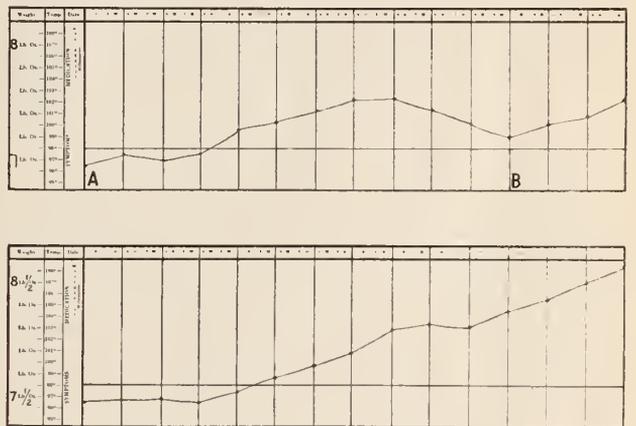

Chart II.—This patient was more perplexing. At A, the diet had been increased to albumen milk with five per cent. dextrimaltose thirty-one and one half ounces daily. At B, one faces a grave problem. Here the six soft, green stools daily, suggest an increasing intolerance of the intestine. The dropping weight curve shows the need of the body for food. Should one treat the intestine and withdraw the food? Should one treat the body and increase? With a child under close observation, in a fairly satisfactory condition and on albumen milk, it is permissible to follow the latter procedure. At B, dextrimaltose was increased to seven per cent. The immediate response of the child's general nutrition to the food led to a proportionate increase in the efficiency of the gastrointestinal tract and within two weeks the stools were normal.

drate in the intestine, while such an increase to an ordinary milk mixture would result in uncontrollable and fatal diarrhea. Thus, albumen milk serves a purpose never intended. It conveys a much higher

carbohydrate through the intestine to the starving body cells than can many of the usual mixtures.

The accompanying curves are representative. The history in each case was typical of a non-thriving child treated with many changes of diet. The physical was the usual malnutrition or decomposition. The clinical diagnosis in each case was alimentary intoxication. Upon tea and small quantities of albumen milk, the children made satisfac-

tory recoveries. The accompanying charts show conditions after three weeks of treatment. Each patient was then eleven weeks of age. Patient one had reacted with normal stools. Patient two still showed five to six soft greenish movements daily. Patient one took daily twenty-eight ounces of albumen milk, later increased to thirty-two ounces. Patient two took daily thirty-one and one half ounces of albumen milk.

CHICAGO BEACH HOTEL.

The Relation of Herpes Zoster to Chickenpox

By WALTER M. KRAUS, A. M., M. D.,
New York.

Of late years considerable evidence has accumulated to show that there may be a common cause for chickenpox and some cases of herpes zoster. Until now, this evidence has been clinical rather than experimental. The striking thing throughout is the occurrence of one disease after the other within the incubation period of chickenpox. The subject has been reviewed a number of times, most recently by McEwen. Certain aspects seem worthy of further consideration and will be discussed after the preliminary outline of the subject.

Considering the relationship between herpes zoster and chickenpox, it must be carefully borne in mind that herpes zoster is more frequently a manifestation of some disease. Cases due to cerebrospinal meningitis of syphilitic or other etiology, to myelitis and syringomyelia, and to various infections other than chickenpox, are very common. Those cases of herpes zoster which follow the extensive use of arsenic must also be included within the symptomatic group. Cases of such etiology must be ruled out, for under such circumstances no relation to chickenpox could be expected.

Herpes zoster may, for practical purposes, be divided into two groups, essential and symptomatic, that is to say, cases in which the primary cause cannot be determined and those in which some of the causes mentioned above are demonstrable. In the first or essential group the symptoms of onset are very often those of an acute infection. Kraus says: "The disease usually begins with the symptoms of an acute infection. There may be fever as high as 102° F., chills, malaise, pain either somatic or visceral, and of the neuralgic type. The patient may be prostrated. At this stage of the disease diagnosis is difficult. Various conditions may be mistaken for it, such as pneumonia, pleurisy, acute abdominal conditions, otitis media, and the several causes of lumbar pain. In children pain may be quite absent, while in adults, particularly of advanced age, the pain is usually very severe, continuous, and of a burning or boring nature. The presence of hyperesthesia over the painful area may assist in the diagnosis. In some cases, the peripheral stage is absent and the first sign is the herpetic stage."

THE THEORY OF THE UNDERLYING FACTORS OF THE RELATION OF HERPES ZOSTER AND VARICELLA.

Low has advanced the following theory in explanation of the coincidence of these two diseases. He believes that the toxin reaches the cerebrospinal fluid via the lymph channels of the olfactory nerves, and affects the spinal ganglia (herpes zoster). This occurs before the infection gets into the blood stream, thus causing a general infection (chickenpox). In this connection it is interesting to note that chickenpox begins in the respiratory tract and that the virus of chickenpox enters by this pathway (Jay F. Schamberg). There are a number of other infectious diseases of the central nervous system, such as epidemic cerebrospinal meningitis and epidemic encephalitis, whose pathway of entrance to the nervous system is by way of the respiratory tract and which are complicated in some instances by skin involvement. For the present Low's theory explains some of the coincidences of the diseases under consideration. However, it is difficult to understand why, if there is a known virus, it should involve the skin in some instances by way of the blood stream, while in others it should affect the spinal ganglia and particularly only two or three, as is most frequently the case in herpes zoster.

THE QUESTION OF IMMUNITY.

The fact that herpes zoster does recur has been taken as an argument against the identity of the two diseases, since chickenpox confers immunity. However, it will be necessary to determine that the recurrent cases of herpes zoster are not of the symptomatic variety, before this argument becomes a potent one against the theory. The argument that patients who have had one of the diseases may acquire the other at some other time of life, must be subjected to the same careful scrutiny.

THE CLINICAL EVIDENCE.

In discussing the relations of these diseases it becomes necessary to consider the possibility, not only of generalized skin eruption which resembles herpes zoster, but also of localized skin eruption which resembles chickenpox. Cases of this kind are sometimes difficult of diagnosis.

A. Generalized herpes zoster and localized chickenpox.—Much has been written of this in connection with its possible relation to chickenpox. The condition may consist of a localized herpetic eruption with scattered aberrant vesicles appearing at the same time, or scattered aberrant vesicles which appear after the herpes has set in. Little is to be gained by a lengthy discussion of this matter. In many cases the examiner has been in doubt as to what to diagnose, herpes or varicella. The same applies to the cases which have been designated localized chickenpox.

B. The occurrence of the two diseases in the same or different but exposed individuals.—1. Cases of chickenpox followed by herpes zoster in another individual: Feer reported the following coincidence: A child contracted chickenpox. Two weeks later herpes developed in a boy of nine who had been in contact with the above mentioned case of chickenpox. Seventeen and twenty days later, respectively, chickenpox developed in two children who had been in contact with this case of herpes zoster. Garé reports two cases of chickenpox in a family of three children, which was followed about two weeks later by herpes zoster in the third.

2. Herpes zoster followed by chickenpox in another individual: Chickenpox follows herpes zoster much more frequently than herpes zoster follows chickenpox. The following are typical case reports: C. Wilson, in a short memorandum, describes the case of a man of forty-nine with herpes zoster of the right lower extremity. Seventeen days later chickenpox developed in his son. Taylor mentions the case of a woman with herpes zoster of the trigeminal nerve in whose daughter chickenpox developed a fortnight later. He cites another case, almost identical, in which two children contracted chickenpox a week or two after having been in contact with a man with herpes zoster. Herderschee records a case of a nursing woman with herpes zoster in whose nursing child chickenpox developed ten days later. Two weeks after that chickenpox appeared in an older child and two weeks after that it appeared in a still older child. Von Bokay recorded thirteen cases of herpes zoster which were followed by chickenpox from eight to twenty days later. A. I. Cooke, in a short memorandum, cites the case of a girl of sixteen in whom chickenpox developed a fortnight after her father had had shingles. Ker reported four cases of chickenpox after herpes zoster. LeFeuvre in his review, noted that forty one of the fifty cases which he had collected belonged in this group. Five of these cases he collected himself. Charpentier, Dingwell, Fordyce, and C. Wilson report cases of chickenpox following herpes zoster. Others could be added. The number of cases of chickenpox following herpes zoster far exceeds those showing the opposite sequence. McEwen estimates the former at forty, of a probable sixty reported cases of both kinds. No reason for this is apparent.

3. Herpes zoster and chickenpox occurring simultaneously in the same individual: This coincidence has also been reported. Low cites the case of a woman of forty in whom herpes zoster was followed in two weeks by chickenpox. Neither of these

diseases was present in the house, though a case of chickenpox had occurred in the neighborhood. Dr. Fairbanks, the assistant resident neurologist at Bellevue, to whom I happened to mention this subject, told me that her little sister of five had had an attack of herpes zoster somewhere between the sixth and ninth thoracic segments, during an attack of chickenpox, and about two weeks after the onset of that disease. Bruijning reports a case of the coincidence of herpes zoster and chickenpox. Goldberg and Francis record the history of three patients having chickenpox and herpes zoster at the same time. Head and Corlett and Richardson have recorded similar coincidences. Other cases are reported.

4. Herpes zoster and chickenpox occurring simultaneously in different individuals closely associated: This relationship of the two diseases has also been reported. Oakes cites an instance of two children in the same household, one of whom had herpes zoster and the other chickenpox. Gray cites an instance of herpes zoster in one of three brothers which had followed within twenty-one days by chickenpox in the two other brothers.

5. Herpes zoster and chickenpox may occur simultaneously in the same individual and chickenpox may then be transmitted to another (McEwen's case).

6. Separate epidemics of both herpes zoster and chickenpox have often been reported. They have been reported together (Heim).

7. Summary: Briefly summarized, cases are on record showing that one disease may be present with, or may appear after the other in different individuals, and that no matter which is first, the other may follow. The sequence herpes zoster—chickenpox is most common. When the diseases follow each other in the same individual the sequence is herpes zoster—chickenpox. This latter may then give rise to either disease.

INCUBATION PERIOD.

It is striking that, when one disease has followed the other in different individuals, the incubation period, with very rare exceptions, has been within that of chickenpox—twenty-one days. When the two diseases have occurred in the same person the interval has not been more than seven days, while it has been as short as two days. Such closeness of occurrence can easily be explained by the time required for the infection to pass from the spinal fluid or ganglia to the skin via the blood stream. This time relationship of the occurrence of the two diseases has impressed many of those writing on the subject.

DISTRIBUTION OF THE LESIONS.

There exists a definite similarity between the localization of chickenpox and herpes zoster. Neither affect the palms or soles. Both have a predilection for the thoracic region. That these facts alone may not be taken as good argument in favor of identity of cause is obvious. But combined with all the other arguments they become of value.

PATHOLOGY.

The pathology of the two diseases is almost identical. The sole difference is that the lesion is unilo-

cular in herpes zoster and multilocular in chickenpox. Scarring follows in both conditions.

PAIN.

The absence of pain in chickenpox is not difficult to explain. There is no nerve lesion. In herpes the lesion is essentially a nerve lesion (posterior ganglia). Furthermore, painless conditions occurring in children in which the diagnosis is in doubt cannot be settled on the basis of the presence or absence of pain, since as is well known, herpes in children is rarely associated with pain.

THE CEREBROSPINAL FLUID.

The argument that the presence of cerebrospinal fluid changes in herpes zoster and the lack of these in chickenpox nullifies the identity of the disease, is untenable. In chickenpox the virus invades the blood. Cerebrospinal fluid changes would not be expected. When it invades the cerebrospinal fluid (herpes zoster) they would. By analogy, when the pneumococcus invades the blood, no spinal fluid changes are present, while when it invades the spinal fluid, there are.

CONCLUSION.

The pathology of the two diseases cannot be used as a basis for or against concluding identity of cause, since it is quite possible that two closely allied poisons might produce practically identical lesions. The same applies to the distribution.

At the present time, however, enough instances of the coincidence of these two diseases have occurred to make it more than likely that they have a common cause, at least when they appear within twenty-one days of each other. The occurrence of herpes zoster without any definite association with chickenpox or other cases of herpes zoster is not an argument against this thesis, since herpes zoster is very often only a secondary manifestation of some other disease.

It appears that the sequence may be in either direction, herpes zoster-chickenpox or chickenpox-herpes zoster. The former is much more common. This gives rise to the notion that when the diseases appear in the same individual, the virus becomes disseminated in the blood, due to the vascular damage in the ganglia. This would explain the aberrant vesicles of generalized herpes zoster. No explanation of transmission of either disease to others is at hand.

Two methods of solving the matter present themselves: 1. Experimental. Up to now, however, no organism or virus has been demonstrated for either disease. 2. By abundant reports of instances of the coincidence of the two diseases and through the efforts of boards of health. Were herpes zoster made a reportable disease, some light would soon be thrown on the matter.

The Management of Children Presenting the Postepidemic Encephalitis Syndrome*

By SYLVESTER R. LEAHY, M.D.,
New York,

Assistant Alienist and Chief of Mental Hygiene Clinic, Bellevue Hospital,
and

IRVING J. SANDS, M.D.,
New York,

Assistant Alienist, Bellevue Hospital, Instructor in Neurology, Columbia University.

In order to manage any mental case logically and scientifically, modern therapeutic methods have made it imperative for one to make searching inquiries into the environment, heredity, birth, infancy and adolescence of the patient in question; for all of these factors play an important rôle in determining the mode of conduct of an individual, in illness as well as in disease. Somatic diseases occurring during infancy and childhood, especially when the intracranial contents are involved in the disease process, leave indelible imprints upon the various factors that collectively determine the type of reaction of an individual to a given situation. While the general practitioner appreciates the profound change of conduct that results from such disorders as hemorrhage in the newborn, meningitis and syphilis, it is only he who has been specially trained in diseases of the nervous system, who is in a position to realize fully the effects of such general diseases as scurvy, rickets, scarlet fever, and enteritis upon normal mental development.

For nearly four years the attention of the best medical minds of the world has been arrested and held by a pandemic disease which attacked essentially the nervous system and has counted among its many victims principally the young adults and children. While the acute phase of the infection has now practically subsided, there are still many sporadic cases reported, and, furthermore, we now are left with a group of individuals who have been handicapped in their efforts of adjustment because of their illness.

In a previous communication (1) we reported a group of children who had had definite attacks of encephalitis lethargica, had made apparent recoveries from the disease, and subsequently showed conduct disorders, which made it necessary for their families to send them to the psychopathic wards of Bellevue Hospital for observation and treatment.

While they differed somewhat in their conduct disorders, they all presented a more or less uniform mental picture, characterized by "purposeless impulsive motor acts, marked irritability, definite attention disorders, distractibility and changing variable moods, inadequate and inconsistent emotional reactions, marked insomnia, and, in two cases, precocious sexual feelings and intense eroticisms." (1) The uniformity in their reactions was such as to make us feel that the disorder was entirely different from anything we had seen previously, caused by a disease hitherto unknown and, therefore, deserving the name of a syndrome.

The following two cases illustrate very well the type of reaction that is met with in these cases. They will also serve to illustrate the additional fact that in many of the cases presenting the postepidemic encephalitic syndrome there may be a reversal of the normal sleeping formula—i e., these patients may be somnolent during the day and restless and wideawake at night.

CASE I.—L. L., admitted January 2, 1920, female, white, aged thirteen years, nine months; native of United States, schoolgirl, at present in 7B grade. Family history was negative. The patient was third in family of four; was a full term normal child; delivery uneventful, weighed eight pounds at birth; breast and bottle fed; walked at thirteen months, talked at same time; had been a very healthy child; had diphtheria at ten years, without complications, and measles as an infant. She had always been a quiet, well behaved normal child until after the present illness.

Present illness.—Began at Eastertime, 1920, when she had a slight respiratory infection; then complained of legs aching and saw double. Following this, she had tic of all the facial muscles; later a twitching of the shoulders was noticed, and with this she made a peculiar grunting noise. The diplopia lasted about two weeks and the other manifestations noted above lasted about the same length of time. About two weeks after the onset of her illness, insomnia developed and she was very restless and apprehensive at night, twisting and turning in bed almost constantly.

Since her illness, the disposition of the child changed entirely; she became disobedient, answered her mother back in a very insolent way and was very fussy about everything. She became very irritable and struck the younger children without adequate provocation. She became very slow in school and her deportment was bad; previously, her conduct in school had been excellent and she had done well. Her mother thought that her poor record was due to lack of attention. She had been retarded in the motor field all summer and talked to herself a great deal. She had a ravenous appetite, lost an interest in housework, which she used to show, she continued to sleep poorly at night, especially the early part, but from early morning she slept well and also slept a great deal during the day. She still continued to be apprehensive, even during the day, and wanted the windows and doors kept locked. Her interest in anything tired easily.

On examination, she showed a very natural attitude; was perfectly clear mentally; realized that her condition was abnormal and was very anxious to

*From the Psychopathic Service of Bellevue Hospital, M. S. Gregory, Director.

get well. She stated that when her illness developed, she was drowsy and that her eyes became crossed and she made all kinds of motions with her face. After that, she said, she did not sleep for six months; now was able to sleep a little. She was unable to offer any explanation for her irritability, except that she had "a French temper" (her father's relatives were born in France). She further stated that she tired easily and that she felt sleepy during the day; also that she felt much different than she used to; that now she felt sleepy in school and was unable to put her mind on things. Her memory and orientation were intact, no delusional or hallucinatory trends were elicited.

Intelligence examination by the Stanford scale showed an intelligence quotient of ninety per cent., placing her in the group of normals, although somewhat retarded. Physical examination showed a well nourished and well developed child, four feet eleven inches in height, weight ninety-five pounds, no cranial nerve palsies. All deep reflexes were equally active; there were no pathological reflexes elicited; she walked in a rather rigid manner, but examination of the individual limbs and muscles elicited no spasticity. General sensory examination showed no disturbances. Eye grounds showed no pathological condition on examination. Her vision was 20/20 in each eye. Blood Wassermann and urinary examinations were negative. She showed normal pulse, temperature and respiratory curve.

During her residence here she was rather excitable at times, twisting her fingers and biting her lips, and she showed difficulty in concentration. At times she had difficulties with the other children. This soon passed, however, and she showed marked improvement. Her sleep at first was a little disturbed but later, under the influence of occupational therapy, this became practically normal. She was discharged as much improved on January 30, 1921.

CASE II.—J. E., male, aged nine years, admitted January 26, 1921. Chief complaint, insomnia at night and somnolence during the day. Unable to learn well.

Family history.—Father was an American born citizen, who, in 1908, at the age of twenty-one, had gone to Germany to establish business associations. He remained there, married an Austrian girl whom he had met in Germany, and established a residence there, retaining his American citizenship, however. The family history, both maternal and paternal, was good for two generations back.

Personal history.—The patient was born in 1911. He was of normal birth and normal infancy; he had had none of the other diseases of infancy except measles. He was considered an average child and learned easily and had acquired a good knowledge of both the German and English languages. At the outbreak of the war, in 1914, his father was not pressed into military service because of his American citizenship. When the United States entered the war, in 1917, the father was held as an alien enemy and the family suffered great privations. They lived close to the fighting zone and were in several air raids. The greater part of the time they were compelled to live in a cellar.

The patient would often have to pass days without any food and was forced to undergo other indescribable experiences. At the conclusion of the war, the family migrated to America. The father was apprehended in Paris and held a prisoner for four weeks, being suspected as a possible German spy. The informant stated that the father was often maltreated by the French police and she had been told many times that he would be shot as a spy. When released, the father's face was badly bruised and the patient suffered great fear at the sight of his father. When they came to America, in February, 1919, the patient got along very well with other children and made excellent adaptation to his new country.

Present illness.—In January, 1920, the patient was taken ill suddenly with fever and restlessness and, later, somnolence. He slept for six continuous weeks. At times he was in delirium, in which he would call to his mother and point at the ceiling, saying there were aeroplanes and Zeppelins around and asking her to remove him to a cellar. At other times in his delirium he would call to his mother and point at the ceiling, saying that he saw his father with a distorted bruised face, saying that there were people eating his father.

At the end of six weeks the fever gradually declined and he began to sit up and his sensorium gradually cleared. In March, his mother took him to the Catskill Mountains, where he remained for two months. Since his return from the mountains the patient had become quite restless, he became rather disobedient, would not mind his mother, and he had a ravenous appetite. He could not sleep at night and would prevent his mother from sleeping. During the daytime, however, he would often go to sleep, even while standing. It was impossible for him to learn readily and in talking he would frequently interpose English words when speaking German and vice versa. He remained indoors the greater part of the day and would not associate with the other children.

At Bellevue Hospital, the patient showed a well developed, well nourished physical condition. His pupils were equal, regular and reacted to light and accommodation. There was no nystagmus; his cranial nerves were intact. There were no tremors anywhere in the body. All superficial and deep reflexes were of the normal type. His gait was normal and his station was steady; he showed no pyramidal tract signs, and no sensory disturbances. His heart and lungs were normal. His pulse was 82, respirations 24.

Mentally, he was at first rather quiet, somewhat forgetful, did not know anything about his clothing, appeared rather restless, and seemed to prefer to be by himself. Would frequently interchange his German and English when speaking. He did not associate with the other children in the ward. He did not seem to be pleased with his examination, coöperated very poorly, and showed considerable irritability. His mental tension was definitely lowered; his memory and retention were somewhat impaired. He showed definite attention disorder and could not hold his attention on one subject for any length of time. Intelligence examination by the

Stanford scale on January 28th showed that he had at that time a mental age of six years four months with an intelligence quotient of sixty-seven per cent. The psychologist, however, wisely added the fact that patient ought to be retested later, in view of his personal history in reference to the unfortunate experiences during the war, as it was quite possible that his difficulties might be due to some other cause rather than to an intellectual defect, and that the mental age and the intelligence quotient obtained at this test were probably incorrect.

The patient was immediately placed with the other children. He required no sedatives nor any milder therapeutic measures. He was kept from sleeping during the day, was allowed to attend his school both in the morning and afternoon and was placed upon occupational therapy. Since that time he gradually became brighter, liked to associate with the other patients, and slept very satisfactorily at night. His condition, though far from satisfactory, indicated that he was on the way to greater improvement.

A mental test, done on February 7th by the same psychologist, placed the mental age of the patient at seven years six months, with an intelligence quotient of seventy-seven per cent. A supplemental note by the psychologist stated that the gain of one year and two months in his mental age was due to the fact that the patient had shown considerable improvement, both in his attitude and general conduct. In the ward, he was less timid and talked more freely and there was sufficient reason to expect further improvement in his mental age.

In presenting our plan of therapy, we have taken into consideration mainly two factors: first, the anatomical lesions occurring in the disease; and second, those psychological factors usually employed in the proper management of any child. In order to understand the rationale of our therapy, it would be opportune at this moment to describe briefly the pathology of the disease process, both in the acute period of the disease and during convalescence. All the necropsy material thus far reported show that the most profound change noted in the brains of the patients in these cases is the intense mesodermic inflammatory reaction. It is true that the ectodermic tissue also undergoes considerable degeneration, as is evidenced by the fact that one not infrequently encounters many nerve cells which are the seat of cloudy swelling, chromatolysis and eccentrically seated nuclei, and others are apparently the seat of neurophagy. There is also considerable neuroglia reaction. But this is practically overlooked when one glances through the microscopic preparations and sees the marked edema, the loading of the Virchow-Robin spaces with lymphoid and plasma cells, the proliferation of the endothelial cells, and the collection of lymphocytes in the nerve tissues.

As explained in our previous communication, the resolving mesodermic inflammatory tissue and the replacement of some of the destroyed nerve tissue by neuroglia scar tissue, act as stimulating and irritating agents to the remaining relatively normal nerve tissue; the latter, responding to this stimulation and irritation in the usual physiological manner, produces various forms of both motor and sen-

sory disturbances and causes the conduct disorder under consideration.

We have divided our therapy into five subdivisions, because we found these to be the salient points which offered the greatest difficulty in the management of these cases. They are as follows: 1, diet; 2, sleep; 3, schooling; 4, psychomotor restlessness; 5, drug therapy.

1. *Diet*.—As pointed out, the brain in these patients is very active, due to the irritability of the nerve tissue, caused by the resolving inflammatory reaction. Nervous activity requires considerable fuel, and this has been shown clinically by the fact that most of the patients have a ravenous appetite. We, therefore, gave them plenty of wholesome food, and at more frequent intervals than ordinarily employed. These patients ought to be fed more frequently than the average child, to compensate for the increased nerve activity.

2. *Sleep*.—We found that the most important factor to prevent the reversal of formula from nocturnal to diurnal sleep, was to keep the patient awake during the day and to keep him occupied with some manual occupation. This occupational therapy caused considerable physical fatigue, and, toward evening, the patients slept very well, in the majority of cases without a sedative. Not infrequently it was necessary to give the more restless patients a dry pack, and, the still more disturbed patients, a wet pack. Rarely did we employ any drug sedative and then only the one that had no cumulative action, the drug employed being paraldehyde. The majority of patients slept very well at night, after several days' residence in the ward.

3. *Schooling*.—These patients were in the formative period of their lives and, while handicapped by their physical ailments, we regarded them in a position to receive some schooling. We tried as nearly as possible to avoid those factors that would tax their memory or attention, as those were the two faculties chiefly impaired by the disease. We therefore, placed them under the charge of the teacher assigned to the ward, who employed essentially those measures that would promote associative ideas and prevent taxing the memory and attention. Manual training, in the form of occupational therapy, was one of the measures chiefly employed. We endeavored as much as possible, to cater to the play instinct that is common in every child, and ordinary games were frequently employed. It is of great interest to study the patient in the last mentioned case, who had apparently gained one year and two months in mental rating, after a residence of only eight days. One should be very careful in rating the natural mental endowment of these patients, as the majority of them will rate far below what their natural endowment really is. With the restitution to normal there is great improvement in the intelligence.

4. *Psychomotor restlessness*.—This we tried to combat essentially by limiting as nearly as possible irritating stimuli from reaching the convalescing cortex. The children were placed among other groups of children and were allowed to play and participate in all forms of amusement. They were never ordered to do things, though gradually en-

couraged to adapt themselves to the routine of the ward. Occasionally we found it necessary to use a wet pack and in the more disturbed cases a warm bath.

5. *Drugs.*—Drugs were rarely used in these cases. We found that, as in other conditions where the brain is the seat of a pathological process, the patients in general reacted very unfavorably towards the drugs employed as a sedative. From the study of conditions of excitement, seen in general paralysis and exhaustive states, we have come to the conclusion that the drugs usually employed as sedatives do more harm than good. Of course, there are times when a sedative must be employed, in which case we used paraldehyde, as that is the only drug to our knowledge that has no cumulative action, if used judiciously, and is, therefore, the least harmful of all sedatives.

In conclusion, we feel that while much might be expected from the plan of therapy outlined in this paper, one should be guarded in giving an ultimate prognosis. With careful management, these patients might be placed in a position to be self-supporting and able to make a proper adjustment. We further feel that they will always tend to show emotional instability and impulsive tendencies and that their brains will always be an organ of lowered resistance.

Remarks on Nephritis in Children*

By A. HYMANSON, M. D.,
New York,

Attending Physician (Children's Service) Beth Israel Hospital, and Visiting Pediatricist to the Jewish Maternity, Bronx, and Beth David Hospitals, New York.

Nephritis occurs in childhood under a great variety of circumstances, including all of the acute general infections. In the absence of gross symptoms it is easily overlooked, largely because of the apparent difficulty of making urinary analyses. These difficulties, however, are exaggerated, and in any case there is no excuse for failure to attempt an analysis. Thus the urine may be caught on absorbent cotton and expressed into a bottle until enough has been secured for the more vitally important tests, or a urinal may be worn for a time—a wide mouthed bottle for girls and a condom for boys. Finally, it is always possible to obtain a catheter specimen, and if aseptic precautions are observed there is no danger from this procedure.

The mere presence of albumin in a specimen of urine free from formed elements should not influence us to exclude nephritis, and in such a case we should make further examinations. While the early albuminuria may be febrile, the picture may change unexpectedly to that of nephritis. The following is a personal case in point. A boy of nine years, who was at the beginning of the third week of a mild attack of scarlet fever, began to vomit off and on, and complain of headache, while his face showed slight puffiness. I had his urine examined at a laboratory twice at three day intervals, and also made almost daily examinations myself. There were always traces of albumin, but neither blood nor casts. At the end of the third week I left town for one day and another doctor was called in because of scanty urine. On my visit the following day I was astonished to find the child very ill with inspiratory dyspnea, hoarseness, and difficulty in swallowing. I depressed the tongue and made a digital examination, discovering a very much swollen

epiglottis. Cultures from the throat and nose excluded the presence of diphtheria. It was out of the question to obtain promptly a specimen of urine—the child was too ill to be catheterized—and before we could have sacrificed the epiglottis or performed intubation or tracheotomy, the patient succumbed. This case taught me never to give an absolutely favorable prognosis even in an apparently mild case of nephritis.

The general prognosis of nephritis in childhood is good or, in other words, most patients recover. It would not be fair to assert that recovery is absolute. It is possible that a chronic latent type of the disease may sometimes persist, but it is more reasonable to suppose that the inflamed organs may suffer some impairment of vitality and invite disease in adult life. In this connection we are discussing only the acute type of nephritis and will mention the chronic form later. In mild cases, recovery is spontaneous, treatment consisting of rest—rest of the patient in bed and rest of the kidneys by suitable diet. In severe cases, active treatment is required; the kidneys do not function and other organs must be made to function for them. We have no specific remedies. The vicarious functions of elimination are hot baths or hot packs, which answer equally well, catharsis, and colonic irrigation. In addition the hyperemia of the kidneys may be counteracted by dry cupping over the loins, followed by poultices. Since the common installation of electric lights in houses, it is possible to employ electric light hot baths. In giving cathartics we must avoid those which irritate the kidneys during elimination and to be on the safe side, should depend on phenolphthalein, citrate of magnesia, cascara, rhubarb, and compound licorice or jalap powder. Sodium compounds, because they tend to increase edema, are contraindicated.

*Read before the Eastern Medical Society of the City of New York May 13, 1921.

The question of diet is all important, but there have been and still are notable differences in opinion and practice. The general tendency is to give too much of both liquids and solids, the former upon the theory that the kidneys must be flushed out, and the latter for fear the patient will become weakened. It is very probable that hunger and thirst cures, by giving the kidneys absolute rest, are quite rational procedures in theory, although hard to carry out. Remarkable recoveries have been seen under such circumstances in which no other measures were used. After the prolonged rest the kidneys suddenly resume their functions. Probably the tendency is to give too much food and drink early in the disease, and too little in the subacute and convalescent stages. During the early days of the severe cases in which marked anuria and edema exist, the intake must be very restricted; even water and milk will not be eliminated, most of the fluid remaining in the tissues to increase edema. This was shown conclusively by Von Noorden, who discouraged the free ingestion of milk, long believed to be the best management of the disease. Milk is further objectionable because it is a vehicle for an excess of protein and also because of its sodium content.

Goepfert and Langstein (1) classify nephritis under three types, acute nephrosis, glomerulonephritis, and chronic nephritis. In the United States the distinction between nephrosis and nephritis is less emphasized.

Nephrosis occurs mostly in diphtheria and cholera infantum. The main histological change is a mild degeneration of the tubules with a marked retention of chlorides and water, but there is no hypertension and nitrogen retention is not marked. Glomerulonephritis follows mostly scarlet fever and angina, where there is some destruction of the glomeruli, occasional hypertension, at times bloody urine, the kidneys might eliminate some water but excrete salt and nitrogenous substances with difficulty. Uremia may follow these cases.

Diet in nephrosis, according to the above named authors, should be liberal, the chief care being to keep down the saline content of the food. The patient may eat bread and butter, vegetables, potatoes, rice, zwieback, fruit, meat and cheese. Most uncooked food is fairly free from saline matter. Half a litre of milk may be given daily, about twelve hundred to fifteen hundred grams altogether in twenty-four hours. Diuretin, one to two grams daily, may be given to antagonize edema.

In glomerulonephritis, the amount of protein should not exceed one and one-half grams to the kilo of body weight, or about ten grams daily, not more than one-third of a litre of milk. The bulk of carbohydrates may be given in the form of lactose about one hundred and fifty grams daily. For not only does this substance furnish the caloric requirement but also acts as a diuretic. Other ingesta comprise thin cereal soups, fruit juices, rolls and butter. If the stomach is intolerant, withholding food for twenty-four to forty-eight hours is advisable. At times, even water or cracked ice is not retained, in which case water should be administered by the Murphy drip method by rectum, or

three to four ounces, hypodermically. Four or six ounces of a seven per cent. solution of glucose may also be given by hypodermoclysis twice daily.

If we assume that the child is out of danger and that the kidneys have begun to function, there should be a gradual return to the normal diet, but an exclusive milk regimen is not desirable from any viewpoint. As a rule the child does not like it, and, moreover, it often actively disagrees. It seems to predispose to autointoxication and bacillary infections and retards convalescence. Some milk may be taken with bread or crackers, cereals, milk toast, rice pudding, coffee or cocoa, baked apples, oranges, grapefruit and lemonade. Meat broths should be reserved for a later period.

If, on the other hand, the case goes on to uremia, or what appears to be such, we must bear in mind that other intoxications—notably acidosis—may cause much the same symptoms. In acidosis there may be suppressed urine, vomiting, prostration, somnolence and coma. Laboratory examination of urine by the discovery of diaceturia, etc., should prevent such an error, and at the bedside there would be acetone on the breath, and hyperpnea—a deep and exaggerated inspiration and expiration, not very rapid and without cyanosis. In passing, I may remark that in any condition of supposed suppression of urine, the bladder area should be percussed, to exclude retention. Conversely, uremia may develop in the presence of free urination and normal output of urine. The laboratory man will, of course, indicate the percentage of urea in the twenty-four hour sample. Normally it should be from two to two and one half per cent.

For the high blood pressure of uremia, several doses of nitroglycerin should be given—one three-hundredth to one two-hundredth grain hourly. In convulsions, bromides and chloral should be followed, if necessary, by morphine, and if this fails to control, by lumbar puncture. As a last resort and very cautiously, chloroform inhalations should be used. In spinal puncture, a test tube of fluid should be withdrawn, which method has been used successfully in uremic headache. Venesection is indicated at the first appearance of pulmonary edema. From a child over five years of age from three to six ounces of blood may be taken. If leeches are used, one leech will withdraw ten c.c. of blood and as much more will flow from the wound. Hence if six are used—three over each kidney—the total amount withdrawn should be four ounces. If much blood is withdrawn, saline infusion of one hundred to one hundred and fifty c.c. should at once follow, the intravenous method being preferable.

But in case the patient with uremia or with threatened uremia has a low blood pressure with cyanotic tendency and cool extremities, nearly all of our resources are contraindicated. Hot baths and packs, venesection and leeches, pilocarpine—if one is in the habit of using it—must all give way to a stimulant plan of treatment, camphor, digitalis, and similar preparations. Regular pulse with increased tension gives a favorable prognosis, other things being equal; but low blood pressure and arrhythmia are bad prognostic signs. In these cases there is always the possibility of collections of fluid in the large

serous cavities, pericarditis, and cardiac dilatation, which affect the prognosis unfavorably.

Concerning chronic nephritis of early life, according to systematic writers there are at least four clinical types of this affection, two of which are so uncommon that they may be left out of consideration. These are respectively chronic interstitial nephritis and a form of chronic nephritis associated with infantilism. The two common types are both of the nature of chronic parenchymatous nephritis and of these the most common and best known are the moderate and severe types, differing in no respect from the same disease in the adult. This may also be left out of consideration under the circumstances, so that there remains for discussion only the so-called benign or mild type of chronic parenchymatous nephritis which is peculiar to early life. This is a very common affection, although less common than the preceding. It doubtless ends in recovery in the majority of cases, under proper management, and perhaps often spontaneously. It would end favorably perhaps in all cases, were it not for the fact that exacerbations occur from a variety of causes and at times serve to transform the mild into the severe type; or, failing in this, to prolong indefinitely the duration of the disease. As a rule, in chronic nephritis irrespective of type, an acute attack is succeeded by a subacute stage which may persist for about a year, after which it is termed chronic. In the form under consideration this order may be reversed and a mild chronic lesion may light up into an acute one or become, as stated, of a more severe type, in either case through various degrees of exacerbation.

In the mild type of chronic nephritis the child presents no definite symptomatology until the urinary examination is reached. He belongs simply to the undernourished type—pale, thin, and underweight, with poor appetite and little energy. Examination of the urine shows some albumin with formed elements in the sediment. There may be a few casts. Red blood cells should not be present, save in acute exacerbation. These findings are quite sufficient to make the diagnosis after orthostatic albuminuria has been excluded by a day or two of rest in bed. It must be remembered that a few formed elements may also occur in the latter condition. In following up these cases, evidences of exacerbation are often seen either in response to an infection, an act of exposure and perhaps from medication or dietetic errors. The albumin in the urine will then be increased and some edema appear about the ankles, while the amount of formed elements will also be augmented and red blood cells will appear. It should be added that exacerbations may appear without any evidence of an exciting factor.

In these cases no diagnosis is complete without blood and urine chemistry and some method for estimating the efficiency of the kidney. Blood chemistry is of importance because there are cases where the amount of urea excreted in twenty-four hours may be normal and the concentration of urea in the blood may be very high. Dr. Hill, of Boston, finds that two tests will cover all the requirements of rapid and efficient means to determine the functional capacity of the kidney. One is the phthalein test,

which has no decisive value if high (because even with eighty or more the kidneys will be damaged), but it is very valuable if persistently low—say below fifty-five or sixty—indicating then badly damaged organs. The other is the Mosenthal two hour test, so-called, in which the specific gravity alone is measured and differences noted between the high and low readings. In this test, the kidneys are always roused to action by throwing work on them. Usually the patient is made to consume (for a brief interval only) an excess of protein—more than is allowed in his diet. Some pediatricists would not use animal proteins in this test, but this caution is probably unnecessary. One gram of salt and two grains of benzoate of caffeine are used to stimulate the renal secretion. In the normal child the differences between the highest and the lowest specific gravities should average eight, while in damaged kidneys they should not be more than one or two.

Another concentration test worth mentioning and easy to carry out is to keep the child the entire day on dry food only (no cereals nor fluids). Collect day and night urine separately. In normal concentration there is a diminution in the amount of urine secreted and a marked increase in the specific gravity up to a 1.030 and over. If there is interference in the concentration, the diminution in the amount of urine is not very marked and the specific gravity will hardly rise to 1.010. The above mentioned functional kidney tests are of great assistance in outlining a diet and the amount of fluid to be allowed.

The treatment is one of complete rest and proper diet with the avoidance of everything which could possibly cause an exacerbation. Diseased teeth and tonsils should be removed and the surface systematically protected from chilling. The question of bathing is a difficult one, but cool baths are in general condemned and in some subjects even tepid baths may be contraindicated. It is hardly practicable to speak of avoiding measles and influenza, although everything possible should be done to prevent exposure to these diseases. If one of these affections or even a bad cold is contracted it may mean an acute exacerbation. The diet should be liberal, with meat once a day. There is no need to make the diet salt poor, but if the child has a craving for salt it should certainly be discouraged. There is a prejudice against meat broths, which may not be rational, but Dr. Hill does not allow them, as they do no good and the patient gets the benefit of the doubt. Water can be drunk freely and there is no prejudice against milk, while there is no ban on fish and eggs. General tonics, especially iron, should be given steadily.

These children should recover, barring accident, in the space of several years. Disappearance of albumin from the urine is no criterion of recovery and reliance should be placed on the negative phthalein and Mosenthal tests and the absence of formed elements and casts in the centrifugalized sediment. The younger the subject, other things being equal, the better the prognosis.

Artificial Feeding of Normal Infants*

By WILLIAM L. ROST, M. D.,
New York.

Although somewhat reluctant to approach a subject about which so much has been written, I feel sure that the observations made in a large clinical experience will be helpful. All fairminded persons readily concede that fads and fancies are observed in the practice of medicine and infant feeding has undoubtedly come in for a great share of this instability; apparently the final word has not been said on this most interesting subject.

Time was when those clinicians who believed in and fed high fat formulas condemning the protein, held sway; then along came observers of equal clinical distinction who asserted that the fats and sugars were the disturbers of peace in artificial feeding; finally others were convinced by clinical experimentation that cow casein was not only tolerated by well children, but that infants with gastrointestinal disturbances were benefited by the administration of a mixture rich in cow casein and relatively low in fat, sugar and salts. These diverse opinions and observations helped not a little to confuse the general practitioner when he was confronted with the problem of artificial feeding. He had been taught at college that high fat and low protein were best suited, but unfortunately he had heard a paper read at a medical meeting condemning this method and suggesting the employment of whey mixtures. Another advised and recommended the memorizing of various tables and formulas he found beneficial. Still another authority insisted that artificial formulas must approximate mother's milk, this necessitating a knowledge of the various percentages of top milk and cream mixtures. His perplexity was increased as he learned of the various malt preparations, dry milks, evaporated milks, and buttermilk and corn syrup mixtures that were used by the experienced clinician, with excellent results. He found himself in a maze and finally gave up in disgust; I do not blame him.

Infant feeding cannot be taught, therefore no attempt will be made in this brief discussion to do more than to give in a concise and simple way the fundamental principles involved and some practical suggestions that have been found useful. One must remember that the art of infant feeding can be acquired only by constant application to this branch of medicine and that a large clinical experience is of paramount importance. It is for this reason that I am of the opinion that the general practitioner should take charge of the normal cases only and those infants who manifest the slightest pathological disturbance should be referred to one of qualified clinical experience.

During my college days Dr. John O. Polak, of Brooklyn, obstetrician and gynecologist, used to insist that all he attempted to do with his pupils was to teach them safe obstetrics; by that he meant that if the doctor was unable to cope with his case he should recognize this early and seek aid before it

was too late. I take this as my text and make a plea for safe infant feeding.

The obstetrician, as well as the general practitioner, are the first to observe the infants from birth and it behooves them to familiarize themselves with the ordinary principles of infant feeding if they are to attempt at caring for these future citizens. They must learn to appreciate what delay and procrastination means when an infant does not take kindly to the formulas that may be prescribed. Do not wait to consult or refer the cases when severe dyspepsia has developed or the infants have become atrophic or are suffering from an acute alimentary intoxication, which in the majority of instances means death. Seek aid just as soon as there is the slightest variation from the normal if you wish to do justice to your patients and save life. I am making this plea in behalf of those little patients who do not need rhubarb and soda and calomel and frequent bowel washings when they are suffering from the results of improper feeding.

It is now well recognized that practically all the digestive ferments are present in the newborn and very young infant; some of these ferments are only mildly active at birth; very soon, however, the infant learns to take care of a fair amount of carbohydrate in the form of cereal decoctions and even well cooked gruels; therefore the infant is prepared to digest fats, protein, carbohydrates (sugars and starches), salts and water.

It is also well established now that cow's milk cannot under any circumstances be made to approximate human milk because of the biological differences; the best that we can do is to give cow's milk in such dilution and quantity as experience has taught us is safe for an infant, at a given age and of a given weight. The prerequisites for a baby to thrive on are the following: 1. It must receive the proper quantity of food calculated in food calories in proportion to its body weight. 2. The food must contain the proper elements (fat, protein, carbohydrate, salts and water) to maintain nutrition and allow for growth, and it must be assimilable. The fats supply heat and energy, add to the body weight by storing up fat, and save nitrogenous waste. The proteins are essential for cell construction and the replacement of nitrogenous waste. The sugars supply heat and energy and replace fat waste or fat deficiency. The salts are essential to growth and development of the tissues of the body and enter into the various chemical reactions of the food and body fluids.

While the composition of human milk gives us a guide as to the digestive capacity of infants, in attempting to feed cow's milk in composition resembling mother's milk, a great deal of trouble due to fat indigestion has been experienced by some clinicians, while others say they have observed no untoward effect in certain normal infants. After studying both sides of the question, and from our

*Read before the Bronx County Medical Society, May 18, 1921.

own experience with a large number of infants of Jewish, Italian, German and Irish parentage, we have come to the conclusion that simple dilution of whole milk making up the deficiency in sugar is safest, simplest, best tolerated, gives the least digestive disturbance, and is readily taken up by the average mother. The latter is by no means a negligible factor in the success of infant feeding.

In order to make clear our conception of this subject it is well to consider the differences between human and cow's milk.

HUMAN MILK.

Fat	4.0	per cent.
Protein	1.5	per cent., casein 0.5 per cent.
Sugar	7.0	per cent.
Salts	0.2	per cent.

COW'S MILK.

Fat	4.0	per cent.
Protein	...	3.5	per cent., casein 3.0 per cent.
Sugar	4.75	per cent.
Salts	0.7	per cent.

Both are amphoteric in reaction when they leave the breast; cow's milk is usually acid by the time the baby gets it; human milk is practically sterile, while cow's milk is not. The fat emulsion is finer in human than in cow's milk; the greatest proportion of protein in human milk is lactalbumin, while in cow's milk it is the casein. The enzymes of the two milks are different and each has a specific serum reaction. Water is the simplest diluent and lactose is the natural sugar; cane and malt sugar are also well borne by healthy children; there is, however, some difference in their effect, which makes it at times desirable to use one in preference to the other.

Milk sugar does not ferment with yeast and is not readily broken down in the stomach, hence in infants who vomit it is preferable to cane or malt sugar. It is slightly laxative and is usually well borne by healthy infants in amounts up to seven per cent., beyond this diarrhea is likely to occur; it is badly borne by infants with a tendency to looseness of the bowels. Cane sugar is mainly used because of its cheapness. It is likely to set up alcoholic fermentation and may cause vomiting, but some infants thrive on it.

Malt sugar is rarely used on account of its expense; the preparations most commonly employed are combinations of maltose and dextrin. In these preparations we have a combination of polysaccharide dextrin and a disaccharide maltose; maltose is a crystalloid, fermentable and dialyzable, while dextrans are reversible protective colloids, nonfermentable and nondialyzable; both are eventually absorbed as dextrose. The advantage gained in the use of these sugars lies in the fact that maltose is readily absorbed and dextrin, through its protective action, aids in the assimilation of the cow's milk; there is slight increase in the water retention, the combined action resulting in a more rapid gain in weight. When the proportion of maltose is greater than that of dextrin, the laxative effect is increased; as a rule more of this sugar can be given than of the others without causing gastrointestinal disturbances.

The starches act as protective colloids, and in this way prevent the formation of tough curds. Those most commonly employed are barley, oat-

meal, and imperial granum; barley is slightly constipating while oatmeal is somewhat laxative; the reverse of these effects has been observed in some infants. After the second month the majority of infants can tolerate cereal decoctions used as diluents, and at six months the average infant can digest well cooked gruels. The starches may be utilized advantageously where there is a diminished tolerance to sugar or fat, so as to make up the deficiency. In those children who have some difficulty with casein digestion, boiling the milk is the simplest means at our command to prevent tough curd formation. The addition of cereal decoction or an alkali such as sodium citrate, two grains to each ounce of milk in the formula, will hinder the formation of large curds.

Having discussed the several principles of practical importance, let us now apply them in a practical way.

1. How to determine what to give.
2. How much at a given time.
3. At what intervals.

In prescribing a given formula the directions must be specific and should be written or printed plainly. The best milk obtainable (certified raw milk preferably) should be used and some fruit juice (orange, pineapple, tomato, grapefruit, prune) should be given after the sixth week; beginning with small amounts diluted with boiled water and gradually increasing up to one or two ounces daily.

To determine a given formula according to the method suggested, it is well to know that one ounce of average cow's milk has a caloric value of 20; one quart of whole milk about 640 to 670; one gram of fat 9.3 calories, and one gram of sugar, starch, or protein 4.1 calories.

Careful energy metabolism experiments carried out by Rubner and Hoebner, Benedict and Talbot, Holt and others have shown that the average normal infant in order to thrive requires about fifty to sixty food calories to the pound of weight up to six months of age, after that from forty-five to fifty. Very active babies require more because they use more; fat, lethargic infants require less because their metabolism is less active and little is used up in energy. Experience has taught that an average baby requires from one to one and a half ounces of sugar in twenty-four hours; this represents 120 to 180 calories. Given an infant four months old weighing thirteen pounds, the approximate caloric requirement would be 650; deduct the amount of sugar, 180 calories, leaving 470 calories to be supplied in the form of whole milk, or about twenty-four ounces. The average four months old infant will take about seven feedings of from five to six ounces, making a total of about forty-two ounces; of this, milk represents twenty-four ounces, diluent eighteen ounces, and sugar one and a half ounces.

When beginning artificial feeding it is advisable to feel your way, give less than the calculated amount until you have determined the tolerance of the patient, and then gradually work your way up. As a safe although not invariable guide, we would suggest up to two months of age about one third milk and two thirds diluent; from two to

four months half milk or a trifle over; from four to six months twice as much milk as diluent; from six to nine months three parts of milk and one of diluent, or even whole milk undiluted.

The amount of a feeding will vary with the size of the infant; some will take two and a half to three ounces the first month, others more; after the second month a safe rule is to feed from one to two ounces more than the age in months, the maximum being about eight ounces—I know that some of our ablest clinicians feed ten ounces or more at one feeding, but in our experience we did not find this necessary. Very young and small infants may require feedings every two or two and a half hours the first month or two, some will thrive very well on a three to four hour schedule;

judgment and careful observation are necessary. Hard and fast rules as to the exact intervals of feeding are irrational because of the variations in some babies of the gastric motility and the amount consumed. It is also well to remember that cow's milk remains in the infant's stomach longer than mother's milk.

To summarize, we in our experience have found it preferable to employ whole milk dilutions, using the caloric method as a check, for the following reasons: 1. It is simple to carry out. 2. Infants thrive better and have less gastrointestinal disturbances. 3. It is more adaptable to the average household. 4. The ready cooperation of the mother because of the simplicity.

2001 GRAND CONCOURSE.

Clinical and Therapeutic Observations on Biliary Disorders in Children

By J. EPSTEIN, M. D.,
New York.

Jaundice of the newborn or *icterus neonatorum* is the first biliary disorder in early life. Statistics from maternity hospitals indicate that about seventy-five per cent. of the newborn become more or less jaundiced on the third or fourth day after birth. This discoloration is transitory, lasting from a few days in the majority of cases to a week or two in some cases, finally clearing up without therapeutic help. The infant does not show any evidence of ill health, the digestion is good, and there are usually no abnormal changes in the color of the urine and feces.

The etiology of this early biliary affection is not definitely known. It may be due to an excessive biliary secretion, with an imperfect drainage through the narrow infantile bile ducts, or to an erythrocytolysis which, in turn, causes an increase in bile formation and an absorption by the general circulation. The erythrocytolysis may be considered as part of the general anatomical and physiological changes that take place in the newborn during the period of transplantation from intrauterine to extrauterine life.

This icteric manifestation must be differentiated from *icterus* due to sepsis, syphilis, hereditary family jaundice, Winckel's disease, and congenital obliteration of the common bile duct. In sepsis there is fever, prostration, and the underlying focus of infection which can be frequently traced to the umbilical region. Syphilis can be diagnosed by the parental history, the fate of previous pregnancies, the symptoms and signs of lues in the infant, and by the Wassermann test. Hereditary family jaundice may be diagnosed by the familial history, the variable degree of jaundice, the absence of bile from the urine, its presence in the feces and by the fragility of the red blood corpuscles. Winckel's disease is rare and is characterized by intense jaundice,

cyanosis and hemoglobinuria. Congenital obliteration of the common bile duct becomes evident from the constantly increasing jaundice, the exclusion of sepsis and syphilis, the occasional subcutaneous and submucous hemorrhages, and the enlargement of the liver and spleen.

Icterus neonatorum requires no treatment. In septic jaundice the underlying infection must be treated. Syphilitic jaundice will clear up under antiluetic therapy. For familial jaundice the treatment is merely symptomatic, while Winckel's disease and congenital obliteration of the common bile duct are beyond therapeutic help.

After this infantile jaundice there is a period of comparative freedom from biliary disturbances till the child reaches the age of three or four years, when jaundice is again prevalent. This second period of biliary disease coincides with the period of the exanthematous diseases. At this age, the jaundice is commonly known as catarrhal jaundice. The diagnosis is usually simple because those pathological processes which cause jaundice in early life are not present at this age; the cholecystitis, cholelithiasis, hepatic cirrhosis, and malignant growths, which are the cause of jaundice in adult life, are too rare in childhood to be of etiological importance.

The cause of this biliary affection is not known. It is a cold wet weather disease, occurring mostly during the cold rainy season and occasionally manifesting itself in epidemic form. Some infection or intoxication is undoubtedly the cause. Gastroduodenitis with an ascending infection through the common bile duct is thought to be the cause of catarrhal jaundice, but gastroduodenitis is of frequent occurrence in children without the complication of jaundice. It is a common digestive disorder, uninfluenced by seasonal variations, and does not affect children in large groups. If gastroduodenitis

should be accepted as the etiology of catarrhal jaundice, it must then be assumed that it is caused by a special type of organism as yet unknown. It is also probable that a hemolytic organism is the cause of this hepatobiliary disease. This organism causes a destruction of many red blood cells and a liberation of a great many infected hemoglobin fragments, which are used as bile material, with the consequent infection and obstruction of the biliary channels. Whether the infectious process along the biliary tract is an ascending or descending one, catarrhal jaundice is evidently not a local disease but a general infection with the hepatobiliary system mostly involved.

From an observation of a large number of children with catarrhal jaundice, I was impressed with the fact that the disease runs through three stages or periods. There is a short but indefinite period of incubation during which time the child is not as well as usual. It is restless, fretful, refuses food, and many have some fever, but there are no definite symptoms or signs. This is followed by a well marked period of invasion lasting two or three days. The child looks ill, sore throat is frequently complained of, and almost all have abdominal pain and general aching. Slight chilliness and more or less fever are present in the majority of cases. Then comes the third or icteric period which lasts from two to three weeks. The child complains of abdominal distress after eating, the appetite is poor, there is occasional vomiting and marked constipation. Some children complain of 'dizziness. A slight afternoon rise in temperature is always present and the pulse, unlike that in adult jaundice, is not slow but may be irregular. The skin may be of all shades of yellow and the child complains of severe itching. The urine is laden with bile and the stools are clay colored. There is a large tender liver and a palpable spleen. This characteristic third period is frequently followed by a definite posticteric fourth period during which time there are often attacks of intestinal indigestion, the appetite is poor and the bowels irregular. The child loses weight and becomes anemic. This fourth stage or period, which may last for weeks, is probably due to some structural or functional disturbances of the liver or pancreas and is a sequel to the acute inflammatory process.

This clinical observation of jaundice in children, extending over several years, which during certain winter seasons assumed epidemic proportions, makes it quite evident that it is a systemic disease. The infection invades the body either through the upper intestinal tract or through the pharyngotonsillar region, finally selecting the liver where it causes structural and functional changes resulting in hepatocholangitis with jaundice. The infection probably extends to the gallbladder and pancreas and is the cause in many cases of chronic intestinal indigestion. It may also have some etiological relation to cholecystitis, cholelithiasis and pancreatic disorders in later life.

Mild cases of catarrhal jaundice are frequently not properly diagnosed and the patients are treated for all kinds of gastrointestinal disorders. These children usually complain of headache and abdomi-

nal distress after eating. The bowels are constipated and there is occasional nausea and vomiting. Not uncommonly there is daily morning vomiting. A careful examination will show the conjunctivæ and skin to have an icteric hue, the tongue coated, the liver slightly enlarged and tender, and the urine and feces indicative of jaundice. Many cases of periodical vomiting and obscure metabolic derangements, which are commonly diagnosed as acidosis, may be found on careful examination to be cases of hepatic toxicosis or cholemia, due to a dysfunction of the hepatobiliary system.

A functional deficiency of bile may be diagnosed in certain cases. These children show a persistent fat intolerance and various dyspeptic manifestations. There is a peculiar sallow tint to the skin, the stools are light colored, and there is no bile in the urine.

While in the majority of cases catarrhal jaundice runs a benign course, it is not as harmless a disease as it is usually thought to be and it should be accorded more diagnostic study and therapeutic care. An apparently mild case may progress to a more severe type. The biliary inflammation may extend to the gallbladder and pancreas and cause either immediate complications or serious sequelæ.

The usual treatment is very unsatisfactory. A few perfunctory remarks about diet and a bottle of rhubarb and soda mixture is all that the child gets. Acute catarrhal jaundice or acute catarrhal cholangitis is an acute infectious disease and it should receive the same therapeutic care as any other infectious disease. The entire digestive and metabolic system is probably affected in this hepatobiliary disease, because the task of the liver is not only to secrete bile but it has also glycogenic, lipogenic and urea forming functions. The bile is essential in the digestion of fat and probably has a stimulating effect on intestinal and pancreatic secretions.

Every jaundiced child should be kept in bed till the jaundice has entirely cleared up. The diet should consist of proteins with a small amount of carbohydrates and a minimum amount of fat. Frequent drinks of warm alkaline water are very useful. This can be prepared by adding a half teaspoonful of bicarbonate of soda, sodium phosphate, or sodium sulphate to a glass of warm water. The bowels should be kept open, preferably with milk of magnesia. A powder made up of pancreatin, salol, and sodium bicarbonate, taken three times a day after meals, I have found very efficacious. Warm applications to the hepatic region and a daily warm bath do much good.

As a therapeutic experiment, I have used some of my jaundice patients as controls and have treated them according to the prevailing idea of little or no care, while the others were confined to bed and given the proper general care, diet and medication. The results fully justified the care and trouble of keeping an unwilling child in bed. In those children who were kept in bed the duration of the illness was much shortened, there was little gastrointestinal upset, the itching of the skin was not so distressing, and there was no aftermath of various complicating effect on the intestinal secretions.

The Prevention of Contagious and Infectious Diseases in a Children's Orthopedic Ward

By WALTER G. ELMER, M. D.,
Philadelphia.

A children's ward in a general hospital is likely to be under quarantine several times during the year, as it is exceedingly difficult to prevent the introduction of contagious disease with the incoming children. The period of quarantine may vary from one to three weeks, during which no children are admitted or discharged. If a disease like measles or mumps finds its way into the ward there may be a quarantine lasting six or eight weeks. Scarlet fever is most difficult to eradicate if the infection extends to several children. In any case the child must be removed to an isolation building and the ward quarantined for a reasonable period.

This naturally results in a considerable loss, as a number of children must be fed and cared for that would otherwise have returned to their homes, and children seeking admission must be kept waiting. Sometimes children are brought long distances by their parents and on arriving at the hospital discover that the children's ward has been quarantined and they must return home or go to another hospital. In a teaching institution the disadvantages are still greater, as the students are deprived, to some extent at least, of the advantages of practical and clinical instruction in the ward, and the regular operating clinics are also restricted.

A children's orthopedic ward of thirty-three beds in one of our general hospitals had been quarantined from time to time, sometimes for a month or longer, and this so seriously interfered with the teaching courses that I endeavored to find some plan by which we could as nearly as possible eliminate the contagious and infectious diseases. It did not seem possible to control scarlet fever but I felt that most of the others could be prevented. The following plan was adopted:

Children who were brought for admission to the orthopedic ward were examined for any evidence of throat infection, rash on any part of the body, and in the case of the girls, a vaginal discharge. The parents were questioned in regard to any recent contagious disease in the home or school or among the child's playmates. Cultures were made from the nose and throat, and specimens obtained from all the girl children to be examined for vaginitis. If these latter specimens were pronounced negative by the laboratory, the child was admitted to a probation room for five days.

If a child had never been vaccinated, that was done some time during the first three days. Every child was immunized with diphtheria antitoxin in this same period. If over two years of age one thousand units were given and if under two five hundred units. On the second day the reports from the laboratory on the nose and throat cultures were received. On the fourth day a second vaginal specimen was sent to the laboratory. On the fifth day after a careful inspection of the child's body and all

the reports being negative, the child was transferred to the ward. Vaginal specimens were sent to the laboratory each week so that a record might be kept of every girl child during her stay in the hospital. The bed pans were sterilized in a large utensil sterilizer that was used for that purpose alone. When a girl patient asked for a bed pan, the nurse took one from the sterilizer. Every bed pan was surgically clean every time it was used.

This plan has been entirely successful. I put it into effect early in March, 1919, and up to this time, the end of June, 1921, the ward has not once been quarantined—a period of two years and four months. About two hundred children are admitted to the ward each year. More than four hundred and fifty children have been admitted during this period if the usual average has been maintained.

Before putting these rules into effect I considered all the features of the plan very carefully and especially in regard to immunizing every child with diphtheria antitoxin. There may be a little risk in this but it is exceedingly slight, and even that may be practically eliminated by injecting about one drop of antitoxin intradermally and waiting three minutes. If no local reaction occurs, the injection of antitoxin may be given in the usual way.

An alternative to this plan is to use the Schick test on all the children and immunize those that are susceptible by the toxin antitoxin method.

As none of the children during this period has developed a contagious or infectious disease it seems likely that their general resistance to infection has been increased by the diphtheria antitoxin. That advantage would be lost if the Schick method was employed.

Every effort should be made to prevent the entrance into the ward of cases of specific vaginitis as the infection may be transmitted to other children before its presence is discovered. The two forms of valvovaginitis, specific and simple catarrhal, are transmissible. The former may lead to serious results while the latter is comparatively harmless. A child with a vaginal discharge should not be admitted to the ward, but should receive proper treatment until cured. It is difficult to determine when a specific case is cured. If the infection has extended into the uterus it is doubtful if the child can be cured in months, and she may be a carrier for several years.

A child may have recovered entirely from the acute infection and have no discharge and yet a positive report may be returned from the laboratory. Or occasionally a child may give one or two negative results and then a positive smear be obtained. It is the child with no clinical evidence of the infection and yet is a carrier of the infection which must be carefully guarded against, as the nurses or doctors in handling such a child might carry the infection unknowingly to another child. It may happen

that after an operation which requires a considerable amount of manipulation as, for example, congenital dislocation of the hip, the child may within a few days present a vaginal discharge and the smears show the presence of the gonococcus. By careful questioning of the mother it may be discovered that the child had a vaginal discharge two or three years previously from which it had apparently entirely recovered. The unavoidable confusion of the soft parts had lighted up the old infection.

The greatest care should be used in the laboratory examinations and they should be made by an experienced bacteriologist. The failure to distinguish between the true and the pseudodiplococcus may result in confusion and embarrassment to those in

charge of the ward. The gonococcus is decolorized in staining by Gram's method, while the pseudodiplococcus is not.

Adult visitors were admitted to the ward on regular visiting days. Each visitor was provided with a gown which completely covered the clothing. The head nurse used her judgment in regard to the presents which were brought for the children. There seemed to be no objection to new books and toys. Certain of the patients were sent each day to the orthopedic gymnasium during the public clinic hours and no harm resulted from this. So far our plan has been successful, and a period of two years and four months is a very fair test.

1801 PINE STREET.

Intussusception in an Infant Six and a Half Months Old

By SOLOMON ROTTENBERG, M. D.,
and GEORGE M. SCHWARTZ, M. D.,
New York.

The following case is reported, first, because of the large amount of intestine being intussuscepted; second, because of a previous gastroenteritis being the etiological factor, and third, because of the uneventful recovery following resection of the large intestine.

CASE.—A female child, six and a half months old, normal delivery, weight seven and a half pounds at birth. Was breastfed for the first five and a half months, and during that time had no gastrointestinal disorder. Five and a half weeks ago the mother noticed the baby had diarrhea, with six and seven stools a day, green and frothy, with foul odor. The child was treated for the diarrhea, but the condition persisted, and the child was losing weight. Three weeks ago the family doctor placed the child on Mellin's food and barley water, but the diarrhea persisted.

Present illness.—On February 24th, the mother noticed a slight streak of blood in the stool. The following day the child had six bowel movements, each of which was streaked with blood. On February 29th the child had six bowel movements, each of which was streaked with blood. The mother also noticed that the baby was cold and had marked pallor. It cried all day, and the mother thought it seemed unconscious at times. The baby did not vomit. The family doctor called Dr. Hermann N. Appel in consultation, who made a diagnosis of intussusception and advised immediate operation.

Physical examination.—Female child, six and a half months old, crying, thighs flexed at abdomen. The child showed marked pallor. The general physical examination was negative except that the abdomen was slightly distended. No peristaltic waves were visible. A large tumor mass about the size of a grapefruit was palpable in the left lower quadrant. Pulse was 130, temperature 98°. A mass was felt high up in the rectum, and there was free bleeding from the anus. The blood count showed

white cells, 14,000; polymorphonuclears, eighty-two per cent.

Operation.—Under ether anesthesia a median incision was made. There was an escape of considerable serous fluid and a large tumor was found in the left lower quadrant. The ileocecal junction, the cecum, ascending transverse and descending colon were found invaginated into the sigmoid, which was reduced by milking the intestine out. All of the intussuscepted gut was very much congested and the mesenteric glands of the entire small intestines were much enlarged. At the ileocecal junction there was an ulcer about the size of a quarter which was surrounded by an area of gangrene which showed impending perforation. The lower three inches of the ileum and cecum, and three inches of ascending colon were resected (including the appendix), the ends of the intestine were pursestrung and invaginated, and a side to side anastomosis was done between the terminal ileum and the ascending colon. The abdomen was closed in layers.

Postoperative course.—The child made an uneventful recovery except for a slight stitch infection. On the sixth day, postoperative, the patient's temperature rose suddenly to 103°, which was due to a double otitis media. After a paracentesis, the temperature dropped to normal and the baby went home on the fourteenth day, perfectly well.

Pathological findings.—Specimen of ileocecal junction including appendix, three inches of ascending colon, and three inches of lower ileum. There was an ulcer about two inches in diameter, circular at the ileocecal junction. The cecum surrounding the ulcer was markedly indurated and edematous. The mesentery of the ileum showed patches of gangrene. At the centre of the ulcer there was a spot covered only by serosa with impending perforation at this site. The mucosa of the cecum showed areas of gangrene and hemorrhage. The ascending colon showed no pathological findings.

Editorial Articles

INFANT WELFARE

It is now recognized by the medical profession that on the health of the child hangs, to a large extent, the prosperity, even the existence of a nation. The general public is awakening to a realization of the truth of this statement, with the consequence that the infant welfare movement has received a great impetus. Various societies have been organized, among them being the National Baby Week Council, in the foundation and organization of which Dr. Eric Pritchard has been largely instrumental. A meeting of this council was held in London on May 24, 1921, at which Dr. Pritchard, who is chairman of the executive committee, presided. In his opening address he said that the three special phases of the work of infant welfare which the council was emphasizing were the importance of breast feeding, the urgent need for some scheme of pension for civilian widows, and the prevention of blindness, with special attention to ophthalmia neonatorum. The National Baby Week Council celebrated its fifth birthday during the first week of July and it was suggested that a combined health and baby week be held in Great Britain in October.

Dr. Mabyn Read, medical officer of health for Worcester, presented an address in which he referred to the success of the efforts which had been made in that city to improve infant life. When he was appointed medical officer in 1891, the infant death rate was two hundred and eight in a thousand. During the years 1900 to 1905 the rate was one hundred and five in a thousand; in the next five years it was one hundred and twenty-four; from 1910 to 1914 it fell to ninety-four; in the next five years it was sixty-nine, and last year figures showed the infant death rate to be sixty-seven in a thousand.

Previous to the founding of the Infant Health Society in 1907 there had been no particular public health activities, though some two hundred of the worst houses had been removed; a small proportion, in a total of about eleven thousand dwellings. The Infant Health Society began with one health visitor but in 1910 the city council gave an appropriation to this society and two years later took over the health visitor as a city official. Though a few classes for mothers were held, no clinics were started until 1917, when a woman doctor was appointed, giving half her time to the clinic and half to school work. In 1919 the society obtained a grant from the American Red Cross Society and

established an antenatal clinic. Milk was provided for mothers and children by the city council. In 1913 dinners were given to expectant mothers and a small amount of dental work was provided for, both of these activities being limited by the finances of the society.

An important factor in the progress of the work was the sympathetic cooperation of the midwives, some sixteen of whom attended about eighty per cent. of the births in the city. The opinion prevailing among the mothers now was that it was a disgrace to have an unhealthy baby, and that good results were due almost entirely to home visiting. At present there were four health visitors and an antenatal centre which was kept full constantly by the recommendations of the midwives.

Miss Eleanor Rathbone, of Liverpool, deplored the lack of provision made by the State for babies, motherhood not being recognized as work of public importance. The poverty period of the ordinary working class family usually came at the time when the mother was bearing children and this had serious effects on the health of the race. Nothing could be more wasteful or extravagant than the present system of neglecting mothers and children.

Dr. Leonard Hill said that health, including the health of the baby, was closely connected with the question of coal. With our present wasteful methods of using coal, only about five per cent. of its energy and heat value was utilized, the other ninety-five per cent, merely polluting the atmosphere and setting up conditions which caused ill health. London and other industrial centres, he said, were now experiencing the benefits of unobscured sunlight as a result of coal shortage, and he instanced the advantages of sunlight and fresh air as shown in the results obtained in tuberculous children in Alpine countries where the children ran about covered only with a loin cloth. The effects upon these diseased children were extraordinarily good. If this life and the open air schools were good for diseased children the same conditions should be beneficial for the healthy. He believed that in London there were only two open air schools, while in New York there were over a hundred.

Professor E. L. Collis said that economy consisted in spending money wisely and well and must not be confounded with parsimony. By a long series of enactments in the interests of economy, during the past hundred years, the country had been nationalizing the care of health. The first test of

spending money wisely was the return of the expenditure. On the credit side was the productive activity, mental and physical, of adult members of society. The results of nationalizing the care of health, however, were not as yet the most economical. In order to have a healthy nation the first need was healthy babies. The standard of health of children at birth was fairly satisfactory and should be maintained or improved. Girls in school should be taught mothercraft. Money spent on health visitors was true economy. It was cheaper to spread a knowledge of fresh air and cleanliness than to patch up casualties in sanatoriums and dispensaries.

In the brief discussion which followed, reference was made to the need of better housing conditions and for supplying children with pure milk in the interests of sound health.

PATHOGENESIS OF POSTOPERATIVE LEUCOCYTOSIS.

If there is an interesting question to study it is certainly that of the various causes giving rise to leucocytosis after surgical operations in general. Why do reactions take place after aseptic surgical acts of the same order as in infectious diseases strictly speaking? Polynuclear neutrophile hyperleucocytosis follows both aseptic and septic operations and occurs in infectious diseases as well. According to Schultze, hyperleucocytosis is merely apparent; it is due to the fact that the leucocytes accumulate in the deep capillaries and afterward emigrate to the superficial capillaries. This theory is both insufficient and inexact and it is enough to examine the rich leucocytic content of the central and superficial capillaries to perceive that there is a real increase in the leucocytes. Roemer and Buchner state that this increase may take place directly in the blood and as proof they refer to the leucocytic masses described by Everard, Demoor, Massart and others, but the latter observers look upon them as leucocytic thrombi circulating in the blood. Schwer and Löwy's theory can only account for leucocytoses without a local focus, so that Metchnikoff's conception is not generally accepted, which attributes the polynuclear leucocytosis to a chemiotaxic action of the bacteria, as well as various substances circulating in the blood.

However, observation tends to show that the process is of a yet more general order and may be produced by various factors, as postoperative leucocytosis proves. Buchner remarked that certain principles resulting from the destruction of tissues or transformation of albumins enjoy the same

properties, and the trauma of the surgical act is undoubtedly itself of a nature to provoke the formation of substances capable of engendering polynuclear neutrophile hyperleucocytosis. Therefore, it may be supposed that operative trauma in itself, no matter how aseptic, may cause reactional leucocytosis due to the transformation of the albumins of the traumatized tissues.

But chemiotaxis itself is not enough to explain all, and it may be said that these substances act on the hematopoietic organs themselves and thus provoke the passage of the leucocytes into the circulation. We know only too well that absolute asepsis is rarely, if ever, realized, so that even the most minute infection, clinically imperceptible, may cause an increase in the white blood cells. Animal experiments confirm these considerations, so that in our so-called aseptic operations the trauma of the tissues probably alone acts in the production of the leucocytosis. It is impossible to carry out a surgical act without manipulating the tissues to some extent and the handling places the tissues in a state of lowered vitality and it may very likely be that these tissues are capable of engendering toxins, the products of cell disintegration.

The slight mononuclear development following postoperative polynucleosis may be due to the necessity of the organism to elaborate substances capable of reacting against the products derived from the albuminoids in order to neutralize and destroy them. However, the quantity of this antitoxin must be very minute because the mononuclear reaction is also trifling and may be in direct ratio to the power of the substances elaborated during the polynucleosis phase. As to the mechanism of the eosinophilia and basophile leucocytosis, their genesis is still obscure.

Levaditi has pointed out that in infections there is a balancing between the eosinophiles and neutrophiles; for example, there will be an eosinophilia with a maximum polynucleosis and a minimum polynucleosis with maximum eosinophilia. It would seem that the chemiotaxic substances reject the eosinophiles and attract the neutrophiles. The former possess the phagocytic reaction but their appearance at the close of the disease shows that their function is to eliminate detritus accumulated in the organisms during the initial phase of the process. Loeper has supposed that possibly the eosinophiles carried substances for repair into the focus of disease.

These theories are interesting but are yet merely hypotheses. There is one certain fact, however, that has been proved by Bouchez and that is that eosinophiles are usually the index to convalescence.

Basophile leucocytosis—mastzellen leucocytosis—appears to follow the same laws as eosinophilia and they likewise appear to be endowed with the same chemiotaxic sensibility and may engender an active leucocytosis.

PHYSICIAN AUTHORS: JOHNSTON,
COWLEY AND CHAMBERLAYNE

The earliest British physician author of whom we have any record was Dr. Arthur Johnston, the Latin poet, born in 1587, near Aberdeen, Scotland. If there were any before Johnston's time, they were not of sufficient importance to be mentioned in any of the standard histories of English literature. Up to the time of Shakespeare (1564-1616) about ninety per cent. of British authors were churchmen of one sort or another. Prior to the Norman Conquest and for a long time thereafter the churchmen seem to have had practically a monopoly of authorship. It was not until the sixteenth century that men of other professions began to enter the profession in any considerable numbers, and even then the physicians with literary ambitions seem to have been few. A few years before Johnston's death, in 1641, Abraham Cowley, who got a medical degree at Oxford on December 2, 1657, began to be popular as a poet, and then came William Chamberlayne, another poet who also was "a doctor of physick." These three were the pioneers, with the possible exception of some inconsequential representatives of the profession.

Johnston was perhaps the best physician of the three—certainly a much better physician than Cowley—and his literary reputation has stood the test of time better than that of the other two. Samuel Johnson praised him as "one of the best of the Latin poets" and later critics have endorsed this opinion. He wrote a collection of Latin epigrams and elegies, a Latin paraphrase of the *Song of Solomon*, a collection of short poems (1637) and a complete Latin version of the *Psalms*, his greatest work. He began his medical studies at the University of Aberdeen, afterwards going to the University of Padua, then the scientific centre of the world, where he got his M. D. degree. Instead of returning to Scotland, he began practising in Paris and remained there nearly forty years. Upon his return finally to Aberdeen he became principal of the University, but soon went to London to practise and became physician in ordinary to Charles I. He remained in London in practice until his death.

Abraham Cowley's connection with the medical profession seems to have been rather slight. Various biographical sketches of him say he obtained his degree "by an order from the government,"

evidently for some political purpose, but the biographers are somewhat hazy as to what this political aim might have been. Cowley was an ardent Royalist and a great friend and assistant of Charles I, going to Paris on diplomatic missions for him and otherwise aiding the cause of the king. When he died, July 28, 1667, he was buried with great pomp in Westminster Abbey, near Spenser and Chaucer, and Charles II said at his grave, "Mr. Cowley has not left a better man behind him in England." The reticence of the biographers as to Cowley's medical degree also applies to his practice. Beyond saying that after he had his degree he went to Kent "to pursue the study of simples" they are silent. He was thirty-nine when he got the degree and died in his forty-ninth year.

Cowley's is a dead name in literature today, at least so far as his poetry is concerned, though in his day he was even more popular than his contemporary, Milton. "During all of Milton's lifetime his fame was obscured and dwarfed by the exaggerated reputation of this writer," says Edmund Gosse, who professed himself to be the last of Cowley's admirers and contended that Cowley's utter obscurity and neglect were far from wholly deserved. Cowley was one of the child prodigies of literature. His first volume, *Poetical Blossoms*, appeared when he was fourteen years old. One of the poems was *Pyramus and Thisbe*, based on the old Babylonian legend which Shakespeare caricatures in *Midsummer Night's Dream*. This was written when Cowley was ten years old and Gosse calls it "an extraordinary piece for so young a child . . . a work which few of the adult poets of that day would have been ashamed of writing." Among his more mature works were *The Cutter of Coleman Street*, a dramatic satire; *Davidis*, an unfinished epic based on the life of King David; *Love's Chronicle*, *The Mistress* and other poems. Although his poetry is no longer read, Cowley still has some vogue as an essayist. His essays, incidentally, were written after he had retired to Kent to study simples, which seems to have been the extent of his medical studies. Charles Lamb found these essays "delicious" and preferred them to Addison's. Taine found the essays "as easy and sensible as his poetry is contorted and unreasonable" and the late John Burroughs carried a copy of Cowley's essays about with him. "Solitude," he said, "seems to bring out their quality, as it does that in some people." They are indeed among the finest essays in the English language.

William Chamberlayne, born in 1619, was a contemporary of Cowley, who was born in 1618. Like Cowley, Chamberlayne also was an ardent Royalist

and during the civil war was one of the most active supporters of the Charleses. He wielded the sword as well as the lancet, as it appears from a passage in his *Pharonnida* that he took part in the second Battle of Newbury. When King Charles II was restored to the throne he wrote a long poem, *England's Jubilee*, in honor of the event. Robert Southey, the poet, said that Chamberlayne was "a poet to whom I am indebted for many hours of delight," but Chamberlayne is almost as obscure today as is Cowley. His chief work was his *Pharonnida*, an heroic poem in five books. "One of the most interesting stories that was ever told in verse," said Thomas Campbell, the Scottish poet and critic. This poem, full of stirring incident, later was made into a novel, under another title, and had a large sale. Although praising the plot of *Pharonnida*, Campbell added that "never was so much beautiful design in poetry marred by infelicity of expression and style that is at once slovenly and quaint." Henry Neele also called *Pharonnida* "a very noble work" and Edmund Gosse points out the close resemblance, in metrical form, of this poem and Keats's *Endymion* and is inclined to regard "the debt owed by Keats to Chamberlayne as larger than has generally been recognized." Chamberlayne's chief work other than *Pharonnida* was *Love's Victory*, a Tragicomedy. Chamberlayne spent practically all of his life as a physician at Shaftesbury, in Dorsetshire, where he died in January, 1689.

GERMAN DOCTORS CHANGE THEIR MINDS

One result of the prevailing degeneration in Central Europe which even the worst enemy of Germany probably did not foresee is the change in attitude of the medical men toward socialization, according to a dispatch from the Berlin correspondent of the Federated Press, dated May 10. This observer states that physicians who before the war were bitter foes of any attempt to socialize medicine have gone over to the ranks of the converts, and that the once obscure little Society of Socialist Physicians is now voicing the thoughts of a great number of medical men.

The basis for this change, if the correspondent reports correctly, is grim economic necessity. With the increased cost of living in Germany and the consequent impoverishment of the people, the situation of the doctors grew rapidly worse. The head of the family, if ailing, still came to the physician of the *krankenkasse* or sick benefit society, but the members of his family stayed away and tried to cure

themselves. As a result, the situation of medical men likewise grew desperate.

"There is the keenest of competition for the 'job'—this is all that it now amounts to—of curing an ailing person, and a consequent demoralization of the medical profession," writes the correspondent. "Quackery is encouraged, for a physician who might otherwise have sent a patient to some colleague who is a specialist on the particular disease in question will now, for economic reasons, hang on to the victim and try to effect a cure."

There is little hope of wealth and glory just now for the German medical man who distinguishes himself, and while the doctors of the *krankenkasse* secure a precarious living, the situation of the others is even more precarious. They are, of course, only sharing in the great nightmare which has fallen upon the professional classes everywhere in the war ridden countries, but their change of heart is significant.

WOMEN AS CAR CONDUCTORS

When the National War Labor Board, after the war, ordered the women discharged from trains, there was a great outcry from the National Woman's Trades Union League, and it was the same in England. No one wants to detract from the splendid service they rendered, nor to deny that it might wisely have been continued if babies—or rather, some satisfactory substitute for them—had been invented, but not the wisest obstetrician could think of anything save the old fashioned baby travelling the same route into the world and demanding prenatal care, and equally postnatal fostering. Any girl might become pregnant. There was continuous standing, and, in England, mounting outside steps, she was only partly sheltered from the rain; the safety of the riding public depended largely on her in rush hours; she had to exercise continuous self control and, instead of a low growled "damn," would answer back to any irritating passenger. There were late hours and seldom any Sunday rest. One or two days a month she would have been better at work under less nervous strain, but that item, of course, prevails everywhere, except that responsibility is here added. I have seen girls adding to the amusement of passengers by snapping at inoffensive people and storming at impertinent ones. "I'm doing what your mother neglected to do," said a red faced, angry conductor, as she smacked a cheeky boy's face, she herself being then liable for a summons for assault.

All this comes from Dr. Anna Howard Shaw's saying that the time has come when women have a right to ask that they shall be free to labor where labor is needed, and tested by their ability to render

service. "No human being can tell what another human being can do," she says. In the case of car work the doctors say that this special work is bad for prospective mothers with nervous dispositions, and a doctor cannot exactly be imagined as actuated by any personal desire to keep women out of any particular job. A girl, too, seldom eats properly; she is content with a "little something" in the form of coffee and sandwiches, eaten hurriedly, whereas a man sits stolidly down to a square meal, then has his pipe and forgets his car until he has to remember it.

LEGISLATION FOR WOMEN AND CHILDREN.

In spite of temporary setbacks, the realization that women as the mothers of the next generation require special protection in industry is being incorporated into law in an increasing number of states. The March issue of the *Monthly Labor Review* recounts a number of these instances. Recent legislation in New Jersey prohibits women from engaging in any industrial occupation for six weeks before and six weeks after childbirth; provides for an eight hour day and a forty-eight hour week in industries now covered by the ten hour law, and prohibits night work between the hours of ten p. m. and six a. m. Wyoming has passed an eight hour law for women except domestic servants. In South Dakota the mothers' pension law has been liberalized to include nursing, medical and hospital care for needy and expectant mothers. Pennsylvania has created a department of public welfare which will have supervision over mothers' pensions, work for dependent and delinquent children, prisons and prison labor, and other activities. Strengthening of the child labor law is recorded in Colorado, New Mexico, Vermont, and Wisconsin.

News Items.

Canada's Birthrate Is Double Mortality.—Canada's birthrate during the year 1920 was 27.47 in one thousand of population, as against a death rate of 13.31 in a thousand.

Jewish Memorial Hospital.—Plans have been completed for the Jewish Memorial Hospital to be erected at Dyckman Street overlooking the Hudson River. It will be dedicated to the memory of the Jewish soldiers, sailors and marines who died in the World War. The completed structure will cost about \$350,000.

Health Records Urged to Safeguard Marriage.—Dr. Max Hirsch, of Berlin, has suggested the establishment of a system of health registrations, to be carefully kept from childhood on, and available to marriage candidates upon mutual agreement. He states that this system would have a tendency to check social diseases and reduce undesirable marriage of the physically ill mated.

Dr. Addison Resigns from British Cabinet.—Dr. Christopher Addison, Minister without portfolio and formerly Minister of Health of England, has sent his resignation to Mr. Lloyd George. Dr. Addison resigned because the housing schemes, which the Government once supported with enthusiasm, had been abandoned.

Medical Societies to Hold Joint Meeting in Kansas City.—The plans for the fall meeting of the Medical Association of the Southwest have been combined with the annual meeting of the Medical Society of the Missouri Valley and the Medical Veterans of the World War. The meeting will be held in Kansas City on October 24th to 28th.

Sheppard-Towner Bill Passed by Senate.—The Sheppard-Towner bill providing for cooperation between the Federal and State Governments in protection of maternity and infancy was passed on July 22nd by the Senate and sent to the House. The bill carries initial appropriations of \$1,480,000 which the States would be required to match. It was passed by a vote of sixty-three to seven.

Doctor Telephones Radio Orders for Operation at Sea.—Dr. Raymond Barrett, of Brooklyn Hospital, recently telephoned instructions, which were wirelessly to sea, how to perform an operation with a herring knife on a man aboard a Standard Oil tanker two hundred miles away. The man had cut his finger with a piece of wire and an infection set in which required immediate treatment.

Death Rate Smallest in St. Paul.—The mortality statistics of the twenty principal cities for 1920 show that St. Paul, Minn., has the low death rate of 10.18 in a thousand and Portland, Ore., a close second, with 11.20 in a thousand. The New York city rate is 12.93, and Denver 17.47. Washington, D. C., had the highest death rate from typhoid fever, Cincinnati for measles, Rochester and Boston for scarlet fever, Buffalo and St. Louis for diphtheria and croup, Pittsburgh for influenza, Denver for tuberculosis, and San Francisco for cancer.

Infant Death Rate Lowest in the West.—The report of the American Child Hygiene Association for 1920 lists cities of over ten thousand population according to the number of infant deaths to a thousand of population. Seattle is first among cities of over 250,000 with fifty-six; Portland, Ore., second, with sixty, and San Francisco, third, with sixty-two. Among cities between 100,000 and 250,000, Houston, Tex., has the lowest infant death rate of thirty-seven; Spokane, Wash., comes next with seventy-one, and Oakland, Cal., with seventy-two.

Cholera in Soviet Republic.—Cholera is rapidly spreading in Russia, the disease being carried by starving refugees from the districts suffering from drought and famine. Over eight thousand cases have been reported in the Russian Republic, three hundred in the Ukraine, forty-eight in Simbrisk and nine hundred in Astrakhan. Cases to the number of 624 were discovered on railway trains in June. One of the chief causes of cholera along the Volga, where famine and disease are at their worst, is the migration of complete villages because of the lack of food.

Start Hartley Foundation.—At the first meeting of the Hartley Foundation, recently granted a special charter by the Legislature, Mrs. Helen Hartley Jenkins, the founder, was chosen president. The members of the executive committee include Dr. Samuel A. Brown, dean of Bellevue Hospital Medical College, and Dr. Thomas W. Salmon. The funds given by Mrs. Jenkins to the foundation, in memory of her father, amount to several million dollars. Special attention will be given to public health, mental hygiene and probation work.

National Health Council Issues Biweekly Reports on National Health Legislation.—Biweekly summaries of national legislation concerning public health have been issued by the National Health Council since last March, when Congress convened in special session. These summaries list and abstract all new health legislation and also report progress on bills previously outlined. The demand for them has been so great that arrangements have been made to distribute copies at twenty cents apiece. They can be secured by addressing the National Health Council, 411 Eighteenth Street, N. W., Washington, D. C.

Personal.—After thirty-one years' service, Dr. Charles P. Thwing, president of Western Reserve University, tendered his resignation on June 14th. He will devote his time to writing.

Dr. Alonzo E. Taylor has resigned from the staff of the University of Pennsylvania and will go to the University of California to conduct special research work on the subject of nutrition.

Dr. George M. Piersol, for thirty years professor of anatomy at the University of Pennsylvania, has resigned to devote his entire time to research work.

Dr. Charles H. Mayo, of Rochester, Minn., received the honorary degree of Doctor of Laws at the commencement exercises of Northeastern University on June 15th.

Dr. Hideyo Noguchi, of the Rockefeller Institute for Medical Research in New York, had conferred upon him the degree of Doctor of Science at the recent commencement exercises of Yale University.

Sir Robert Jones, of London, Dr. Carlos Chagas, of Brazil, and Dr. Herbert Charles Moffitt, received the degree of Master of Science at the commencement exercises of Harvard University held on June 23rd.

Dr. Alfred S. Burdick has been elected president of the Abbott Laboratories to fill the vacancy caused by the death of Dr. W. C. Abbott. Dr. Burdick has been closely associated with the Abbott Laboratories for over seven years.

Dr. and Mrs. David E. Hoag, of New York, sailed for Europe on July 21st. After an extensive tour they will return to New York in November.

Dr. Henry W. Frauenthal, medical director of the Hospital for Joint Diseases, New York, sailed on July 27th to visit the various modern hospitals in England, France and Italy.

Dr. L. Duncan Bulkley, of New York, has retired from the active practice of dermatology, to devote his attention to consultation practice and to the treatment of cancer. He has turned over his dermatological practice to his former associate, Dr. A. Schuyler Clark.

Postgraduate Medical School in Vienna.—The dean of the Vienna Medical Faculty has announced that the facilities for study are now the same as before 1914. The professors, doctors and assistants are ready to resume the teaching of graduate physicians in the same manner as before. The total number of beds in the Allgemeines Krankenhaus in Vienna available for teaching purposes amount to thirteen hundred. The opportunity for observing postmortem work is also the same as formerly, the number of autopsies being about three thousand annually. The official lectures and courses are delivered in German but special arrangements can be made for private English courses. Further information may be had by addressing the editor of the *Wiener medizinische Wochenschrift*, Vienna, IX., Borsellangasse 22.

Died.

ARRINGTON.—In Murrayville, Georgia, on Saturday, July 2nd, Dr. John D. Arrington, aged thirty-nine years.

BAER.—In Pittsburgh, Pa., on Sunday, July 10th, Dr. George Franklin Baer, aged thirty-seven years.

BEARDSLEE.—In Rye, N. Y., on Friday, July 8th, Dr. Frederick M. Beardslee, of Manchester, N. H., aged forty-six years.

BEEBEE.—In Buffalo, N. Y., on Friday, July 15th, Edwin L. Beebee, aged fifty years.

BURRITT.—In Washington, D. C., on Wednesday, July 6th, Dr. Alice Burritt, aged sixty-seven years.

CORNELL.—In Wappingers Falls, N. Y., on Saturday, July 16th, Dr. Isaac Martense Cornell, aged seventy years.

COX.—In Sandy Creek, N. Y., on Sunday, July 17th, Dr. William H. Cox, aged eighty-two years.

DRAKE.—In Detroit, Mich., on Tuesday, July 5th, Dr. Harlow B. Drake, aged seventy-two years.

DAVIDSON.—In Parkersburg, W. Va., on Wednesday, July 13th, Dr. William Johnson Davidson, aged fifty-four years.

D'AVIGNON.—In AuSable Forks, New York, on Saturday, July 9th, Dr. Francis J. D'Avignon, aged seventy years.

DAVIS.—In Patchogue, L. I., on Friday, July 15th, Dr. Milton Burr Davis, aged thirty-eight years.

ELLIOTT.—In Highlands, N. C., on Sunday, June 26th, Dr. John B. Elliott, aged seventy-nine years.

ERHARD.—In Syracuse, N. Y., on Thursday, July 7th, Dr. Philip Erhard, aged forty-four years.

FEHR.—In Allentown, Pa., on Saturday, July 16th, Dr. Howard A. Fehr, aged fifty-one years.

GALLIVAN.—In Boston, Mass., on Wednesday, July 13th, Dr. William J. Gallivan, aged fifty-six years.

HERMAN.—In Long Branch, N. J., on Tuesday, July 12th, Dr. Henry Herman, of New York, aged sixty years.

HIXSON.—In Cambridge, Ohio, on Friday, July 8th, Dr. George W. Hixson, aged forty-nine years.

JANSING.—In Cushing, Okla., on Sunday, July 10th, Dr. Joseph Henry Jansing, aged thirty-seven years.

MIDDLEDITCH.—In Barneveld, N. Y., on Monday, July 11th, Dr. James Middleditch, aged sixty-six years.

MORRISON.—In Los Angeles, Cal., on Sunday, July 3rd, Dr. Norman H. Morrison, aged sixty-eight years.

ROBARDS.—In Columbus, Ind., on Thursday, July 7th, Dr. Richard B. Robards, of Harrodsburg, Kentucky, aged forty-five years.

ROSS.—In Grand Rapids, Mich., on Thursday, July 14th, Dr. William H. Ross, aged seventy-six years.

SILER.—In Mercer, Tenn., on Monday, July 4th, Dr. Manly J. Siler.

SMILEY.—In Philadelphia, Pa., on Tuesday, July 19th, Dr. Edwin R. Smiley.

STATON.—In Tarboro, N. C., on Friday, July 1st, Dr. Lycurgus Lafayette Staton, aged seventy-one years.

TALBOT.—In Raquette Lake, N. Y., on Saturday, July 16th, Dr. Robert Bancker Talbot, of New York, aged sixty-eight years.

WEEDON.—In Eufaula, Ala., on Saturday, July 2nd, Dr. Walter R. Weedon, aged forty-eight years.

LONDON LETTER.

(From our own correspondent.)

LONDON, June 4, 1921.

Smokeless Fuel—The State and Housing—The Prevention and Treatment of Tuberculosis—Postgraduate Instruction in Glasgow.

A smokeless fuel is a desideratum from many points of view, not the least of which is that of health. In London this question is one of supreme concern, and that the subject of low temperature carbonization and smokeless fuel is arousing increased interest and attention was shown by the large audience which came to the Royal Society of Arts, London, on April 13, 1921, to hear Professor H. E. Armstrong discourse on the subject. The professor has long given prominence to his personal conviction as to the great possibilities of the newer method of carbonization as a means to the more efficient utilization of coal, with the recovery of important byproducts and a step toward the reduction of atmospheric pollution. Professor Armstrong referred to the natural store of products, chemical and power, in the form of coal, the great asset and salvation of this country's progress.

Reviewing the history of the methods of direct consumption and indirect treatment, he emphasized the appalling waste which had resulted, waste now proverbial. Coming down to modern times, the work done by Parker and Jones was sketched, and some indication of the scale of operations at Baraugh given. The methods of low temperature carbonization have for some time been under critical review. Totally diverse opinions and convictions are forthcoming as to the efficacy of the several processes. These depend to some extent upon the point of view. As a source of heat and power, the gas engineer may want to adopt a British Thermal Units basis of adjudicating the results. From the point of view of oil production in times of emergency and shortage, the tar distillates would increase in importance. From the domestic and health points of view, a sufficiently compact, easily burnable product is the chief desideratum. The economic adaptation of low temperature carbonization processes is a matter upon which a full and frank discussion would doubtless be welcomed in many quarters.

* * *

Sir Alfred Mond, who has been appointed Minister of Health in the place of Dr. Addison, made an important announcement as to the future policy of the Government in regard to housing to a deputation from the Association of Municipal Corporations. Sir Alfred dealt with the question of commitments into which local authorities have entered, and said that, in view of falling prices in material and labor, every effort must be made to obtain modifications of the contracts already let. The general housing subsidy extends only to July next year, and "it is not impossible," the Minister observed, "that the Government may be ready to enter into another scheme, should it be necessary." The National House and Town Planning Council, in the course of a statement, said that the fall which has recently taken place in the cost of cottage building is warmly welcomed by the housing committees of local author-

ities as removing yet another of the difficulties which have delayed the fulfillment of a national duty. The decline in cost varies greatly from district to district. Compared with the tenders submitted in September, the reduction is in some areas equal to twenty per cent. This reduction in cost, it is stated, is in some measure due to the steady desire of employers and operatives alike to fulfill, in respect of housing, their duty to the rest of the community.

It may be said that the erection of houses has been the great stumbling block in the way of carrying out the schemes of the Ministry of Health. This was the first and most important plank of their platform. It has been long conceded that the bad and indifferent housing accommodation of the masses of Great Britain, especially perhaps in the cities, although it is woefully inadequate in the rural districts, was chiefly responsible for the prevalence of ill health and lack of development in all parts of the country. The slogan of the Ministry is prevention of disease, but how can disease be successfully prevented while domestic hygiene is as it is? Obviously, then, the first and most essential step in the direction of prevention was to provide a sufficient number of hygienic houses.

Dr. Addison and his colleagues fully grasped this fact, and proceeded with plans to remedy the deficiency. But they do not seem to have quite understood the state of affairs that confronted them. They sketched an ambitious plan for building houses on a wide scale. So far so good, but they had not counted the cost. It was found that to build houses conceived on a modest plan would cost so much that workingmen could not afford to pay the rent, and that the greater part of the burden must fall on the ratepayers. The ratepayers, taxed already almost past endurance, strongly objected, and so the projected housebuilding has been extremely slow. It is to be hoped that a satisfactory housing scheme will be ultimately carried into effect.

* * *

The prevention and treatment of tuberculosis is a subject of perennial interest, not only because of its manifest importance but also because of the diverse views which exist regarding the disease. There are still many unsolved problems with regard to tuberculosis, and if advance is to be made in prevention and treatment these problems must be earnestly grappled with and some of the obscure features elucidated. In many parts of England there has been an increase of tuberculosis during the past few years, and this has been the case in other parts of the world.

Dr. Sidney Barwise, in his annual report for 1919 as medical officer of health for the County of Derby, provides some interesting facts and makes some pertinent remarks on tuberculosis. It is pointed out that only a few years ago the generally accepted view was that phthisis was due to inhalation of tubercle bacilli in dust from dried sputum, and that over fifty per cent. of glandular and abdominal tuberculosis was due to the consumption of milk containing the bovine type of tubercle bacillus. Investigations on the portals of entry into the body of the specific microorganism have modified our

views on this point. A leading authority, I. M. Pottenger, has recently described tuberculosis as primarily a disease of the lymphatic system, and there is a considerable amount of evidence in favor of the view that the tubercle bacillus gains access to the body through the tonsils or intestine. The droplets sent out in coughing by a person in certain stages of the disease are probably one of the chief sources of infection. Walsham, in 1903, called attention to the tonsil and the cervical glands as a common channel of entry. Beatty and Carnegie Dickson believe that the most frequent mode of entry in the human subject, except in the case of young children, is by way of the tonsils, and perhaps in some cases by way of the teeth. The bacilli pass to the cervical glands and into the lungs by way of the peribronchial lymphatics. From the root of the lung the path of infection may be outward and upward, involving the apex of the upper lobe, or it may spread fanwise and involve the pleura. There is now fairly general agreement with Sanarelli's view that man only survives by having acquired immunity as a result of a mild attack in early life. Support is, of course, given to this view by the large proportion of bodies showing either active or healed manifestations of the disease at postmortem examinations made upon persons who have died from other causes.

Among the practical suggestions made by Dr. Barwise to prevent the spread of tuberculosis are better ventilation in houses, better facilities for washing, and better places for storage of food. The efforts of health visitors should be concentrated on preventing infection during the first few years of life. The child should not be allowed to crawl on the kitchen hearth rug, but have a clean, washable crawling rug, and its hands and face must be washed before each meal. If infected during the first year of life, the result is almost always fatal, and children should be removed from tuberculous mothers, as Bang, of Copenhagen, removed the calves from tuberculous cows. Moreover, the campaign against tuberculosis in cattle must be continued, and until milk is available from certified tubercle free cows that given to infants under two years of age must be sterilized. It must be remembered, however, that the child has to acquire immunity. It cannot always be kept wrapped in cotton wool. Dr. Barwise, therefore, thinks that after it has reached the age of two years it should take its risk in acquiring immunity through a localized tuberculosis by allowing it occasional small doses of the ordinary milk of commerce.

* * *

According to the correspondents of the *Lancet*, April 2, 1921, in Scotland, for many years postgraduate instruction in medicine has been given in several Glasgow hospitals, but only in the early part of 1914 was a special endeavor made to organize a permanent, comprehensive postgraduate teaching scheme for Glasgow as a whole. The outbreak of war delayed further progress until 1919, when an emergency postgraduate course was organized and carried on in the summer and autumn. The course was highly successful, and the committee in charge felt justified in recommending the institution of a

permanent scheme. A scheme of this kind was adopted on March 2, 1920, at a joint meeting of the Faculty of Medicine of the University of Glasgow, and the General Committee for Postgraduate Medical Teaching, which had been appointed in 1914. The various teaching institutions and teachers taking part in the scheme constitute an association the business of which is managed by a board elected periodically by them. The chairman of the board is Sir Donald MacAlister, and the vice-chairman Sir Hector C. Cameron. To inaugurate the scheme, the board arranged a series of weekly demonstrations for practitioners, extending from November, 1920, up to May of this year, and the number of practitioners taking advantage of the series is said to be satisfactory. For the ensuing summer and autumn the board has arranged a comprehensive course of instruction for medical practitioners extending from May to October. Most of the Glasgow hospitals are taking part in the scheme, which has been arranged as far as possible so that a practitioner who so desires may occupy the greater part of each day attending classes open to all qualified medical men and conducted independently of the undergraduate courses. A practitioner may enroll for one or several classes, and may attend for one or more months, at his discretion. The board has also had in view the provision of facilities for young graduates and others who may wish to obtain a closer acquaintance with hospital work in one or other of its branches, and who are prepared to give the necessary time. Arrangements have been made whereby a limited number may become attached to wards or outpatient departments nominally as clinical assistants, for definite periods throughout the year. As such they would work under the direct supervision of the physician or surgeon in charge and carry out such detailed investigations as directed. A young graduate wishing to specialize in children's diseases, mental diseases, tuberculosis, venereal diseases, or other subjects, should find such training invaluable. It has long been felt that Glasgow, in the midst of a vast industrial population, should become one of the leading centres of postgraduate medical teaching.

The question of postgraduate medical teaching is arousing a good deal of interest now among members of the medical profession here, although not so great interest as the obvious importance of the subject would seem to demand. As has been pointed out several times in this letter, London is an ideal centre for postgraduate teaching, certainly in wealth of material equalled by no European city and surpassed only possibly by New York. Of course, the situation of London as a medical centre is greatly superior to that of New York. However, a great deal of organization is required before London can compete with Berlin and Vienna, at least as these cities were before the war. It is likely, too, that if the schemes formulated to make of London the Mecca of postgraduate medical students, especially of American postgraduate students, fail, that Berlin and even Vienna may regain their pride of place. It is encouraging to learn that the Glasgow medical profession is taking time by the forelock in this direction.

Book Reviews

HIPPOCRATES.

The Genuine Works of Hippocrates. Translated from the Greek with a Preliminary Discourse and Annotations. By FRANCIS ADAMS, LL. D., Surgeon. Two Volumes in One. New York: William Wood & Co., 1921. Pp. v-366.

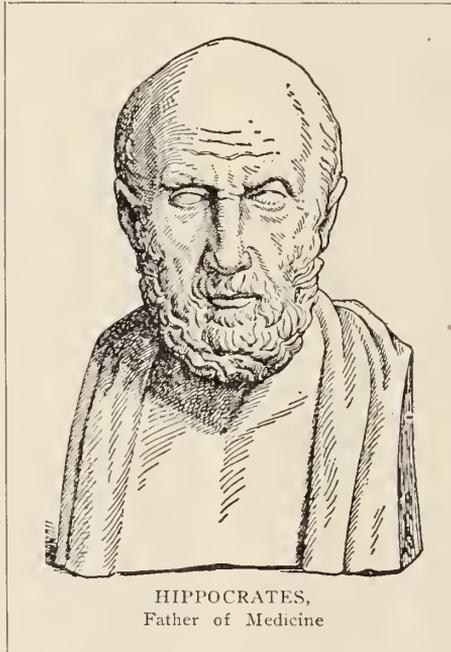

In this edition of the translation of the seven books of Paulus Ægineta, Dr. Adams in 1844 says he is sensible of the growing conviction in the profession of the value of ancient authorities. He has been in his grave sixty years and we again entertain the same conviction after an interval almost as long during which the medical profession has not had that conviction at all. In the days of Adams's bright hopes Sprengel's history, the best by far ever written, had passed into the French edition. Kühn, a living monument of industry and erudition, was but recently dead, Daremberg was beginning his career, Ermerins, Coray, Grimm, Greenhill, Littré above all, were marking the epoch by historical research in medicine and Adams's hopes had full justification, though they had no realization. With the death of Adams (1861) that epoch had all but closed and Daremberg, living eleven years longer, left much work unfinished and still more, apparently, unpublished in the débâcle of 1871, and when France arose again professional interest in that branch of medical knowledge was practically extinct. "Know thyself" is the first apothegm the wisdom of age ladles out to youth. How the medical profession is going to know itself without knowledge of its birth, adolescence and vigorous manhood surpasseth understanding indeed. What are we? Whither are we going?—The problem for the philosopher and the problem for the prophet—it is quite futile to consider until we have some idea whence we come.

We are now entering upon a revival of interest in the history of medicine, borne on the crest of a wave of angry protest against the long raging abuse and insults which men of science, for at least a generation, have heaped upon the cultivation of the humanities. The folly of discarding the granary which has fed human thought for two thousand years, because the harvest was abundant in the fields around it, is now only too apparent. This harvest, it is true, had already swelled to portentous proportions thirty years ago, but even then the evils of a narrow specialism had begun to be fully manifest. I doubt if for many years we can hope for a renaissance of that fruitful interest in the history of medicine which preceded the rise of modern path-

ology, of synthetic chemistry, of bacteriology, but at least let us beware of the silliness of imagining that these *et alia similia* are the only fields worthy of culture by medical man.

If then we are to find in the pulsations of world thought an explanation of why we have not seen a second edition of Adams's *Hippocrates* in a period of more than seventy years since its first issue under the ægis of the Sydenham Society, we must realize we are up against a sort of cosmic law. This, if true, also is ample to explain why no other author has given us another and a better rendition of the works of the great Hippocrates. But perhaps it is not true, perhaps it is because men's minds were so widely diverted to, so powerfully attracted by the great discoveries made possible by the inventions of

physical science, by the microscope and a hundred other scopes and meters, that they were drawn away from the ancient sources which still exist. Adams's translation of *Hippocrates*, the only one so comprehensive in the English language, still exists for us and though in America we have it only in this bulky, fragile, one volume form of reprint, the profession owes its sincere thanks to the publishers for making it accessible to us in any form. It cannot compare in scholarship with Littré's great work. No translation unaccompanied by the text lends itself to serious critical study. *The Preliminary Discourse* is of historical value, but this also suffers from the absence of the Greek text. Nor has Adams's edition the value of his treatment of the Paulus

Ægineta. The commentaries to that, including extensive though not always exact and specific references to all Græco-Roman and Arabian writers, dealing with the same points, are invaluable to the student and all but unique. By this alone he could claim rivalry in service to medical history with the great, if not encyclopedist, the encyclopedic Frenchman. In his edition of *Arctæus* Adams showed he too could edit a Greek text and it was a serious oversight, either on his part or on the part of the Sydenham Society, that the text he used does not accompany his translation. In its absence there is little use in speaking of its fidelity of rendition despite his protest that he paid more attention to faithfulness in this than to elegance in diction. Certainly no reader will accuse him of the latter, but he occasionally will have reason to complain of his obscurity and to suspect that at times he adds his own incoherence to that of an ancient manuscript.

Litré's work is open to no such uncharitable conjectures.

The question of the authenticity of the Hippocratic books has always been a baffling one, but in its pursuit so much is elicited of an historical and literary nature that it is, incidentally and in itself, interesting and instructive and such it will probably always remain. It can only be touched upon here and an enumeration of all its canons even is impossible. Adams urges that if we are to be at all influenced in our judgment of the genuineness of the various books of the Hippocratic Corpus by their style and contents, we must first establish in our minds which ones we are to regard as the style and opinion of Hippocrates as standards by which to judge the others. We have no resource for this but authority and we have no authority ancient enough to make it impressive. Erotian and Galen lived, one about five hundred and the other about six hundred years after the birth of Hippocrates, probably a little longer afterwards if anything. The former gives no reason for the books he selects as genuine and Galen gropes in much the same way as we do. So this canon of criticism, this basis of comparison upon which, in our hero worship, we are prone to lay the most stress we perceive to be an exceedingly shaky one. Such being the state of the matter a critic of much later times feels himself quite at liberty to differ with Galen as to what is worthy of Hippocrates and what is not and in his opinion he is likely, if this is the only rule he goes by, to be largely prejudiced, at least as to the real doctrines of Hippocrates, by the prevailing fads of his own epoch. From this Adams, despite the exceptional clearness with which he defines this aspect of Hippocratic criticism, largely suffers and even Litré does not escape its influence. Nevertheless it is not always fallacious. For instance, all agree that *The Aphorisms* is a genuine book, but to assert that a very large minority of the aphorisms are from the hand of the Father of Medicine is to brand him as a blathering idiot. A few of them inevitably arouse contempt whatever the stage of our medical evolution may be.

The etymological, idiomatic, linguistic guides to criticisms of authenticity are excluded in the face of a translation without a text. In Adams's day archeology hardly at all controlled the historical data, and here is an opportunity for the modern critic to find a new point of view from which to review the matter, but in this field of Hippocratic interest as well as in others the modern commentator has an especial advantage in the possession of a hoard of knowledge in regard to primitive man which practically was not existent at all until many years after Adams's death.

He and Litré being contemporaries one need not be surprised to find *The Genuine Works of Hippocrates* correspond very closely indeed with the works which are regarded as genuine by the great French savant, but Grimm's list amounted to only five. The list of Litré runs to thirteen and Adams looks with favor on seventeen as being authentic, but he is in doubt as to five or six he has included, while Litré thinks perhaps he has excluded too many. Adams is not at all satisfied with the genu-

ineness of *Ancient Medicine* and Litré is quite sure *The Sacred Disease* is not from the hand of the Master. The former book is surely of the very highest rank among the works of Greek genius and the latter is plainly worthy of the hand of the Father of Medicine. So it must be acknowledged that the sort of Hippocratic criticism I have singled out for mention is not always open to the objection of the bias of the critic.

The plainly spurious books which are found in the Litré edition but are excluded by Adams's title, a little presumptive one may be permitted to think, in themselves throw much light not on Greek medicine alone, but on this very question of authenticity. Some of them are quite evidently the products of a later generation than that of Hippocrates II, one or two are probably largely anterior to it in origin, some are the work of ignorant and superstitious men, some probably not of medical men at all, but, genuine or spurious, they all form a Corpus of absorbing interest to the student of the progress of human thought and a collection of writings which are scarcely less so to the broad minded student of medicine.

LAW AND PSYCHIATRY.

Das Eherecht der Geisteskranken und Nervösen. By Prof. Dr. A. H. HÜBNER, Oberarzt für Klinik. Bonn: A. Marcus und E. Weber's Verlag, Dr. Jur. Albert Ahn, 1921. Pp. 87.

This little book has its value to psychiatrist or jurist as a comparative study of conditions which pertain in this as well as in the author's country. It is a stimulus to the mutual interest of psychiatrist and jurist in testing the laws regarding marriage as to their accordance with the actual conditions which they presume to regulate or to remedy. It is a commonplace of knowledge that such laws everywhere fall short of such aim. Hübner has here in a somewhat more definite way pointed out the actual discrepancies between theory and fact. In doing so he shows that the sciences of psychiatry and jurisprudence have not been idle during the twenty years of the existence of the present laws in Germany in improving interpretation and application of such laws. He shows the difficulties which lie in the way of exactness of diagnosis of personal condition, of the mental disease or other matters and how therefore at best general laws are either too sweeping or too restricted to cover individual situations. So much the more then is there necessity for broad and just psychological and as well as psychopathological consideration of each case and of the reform of the whole body of laws. He reminds his readers of the sense of justice which actuates the mass of people and which makes objectionable the subterfuges that have to be resorted to under imperfectly fitting laws. These same people are at the same time so driven by economic needs and by life hunger that they must take up with even imperfect aid. One could wish that Hübner had enlarged upon the psychological and psychiatric aspects of the situations in many cases and made a fuller treatise of the subject. He has given fruitful suggestions, however, for the furthering of his avowed purpose, to aid in the preparation of more scientific foundations for the law of the future.

SQUINT.

Squint. Its Causes, Pathology, and Treatment. By CLAUD WORTH, F. R. C. S., Consulting Surgeon to the Royal London Ophthalmic Hospital (Moorfields); Consulting Ophthalmic Surgeon to Queen Mary's Hospital for the East End. Fifth Edition. Philadelphia: P. Blakiston's Son & Co., 1921. Pp. ix-242.

Five editions within the space of some seventeen years is indeed an enviable record that any medical author may be proud of, the more so as the work is on a narrow special subject that appeals to a limited circle of readers. A medical best seller must possess peculiar qualities to have obtained such a success; and foremost among these we consider the clarity of style and simplicity of exposition, combined with an absence of dogmatic or supposititious reasoning that cloud and obscure many a thesis. Thus the book is made very readable and easily accessible to the general practitioner, we are almost tempted to say to the average intelligent layman. At the same time the specialist will find many an interesting page that he may peruse most profitably.

We were especially impressed by Chapter X on Treatment of Squint, with illustrative cases, an array of clinical cases of particular interest and instruction as their histories are gone into most minutely and conscientiously, extending over a period of years, thus enabling the reader to follow up and participate, as it were, together with the author in the treatment of the cases, and analyze the results. The authoritativeness of the author's conclusions, whether one agrees with him or not, may be gauged by the fact that he had kept detailed notes of every case of squint which came under his observation since 1893, and his experience was thus drawn from an enormous mass of material, both clinical and from private practice. For the last twenty years he was gradually weaned from doing simple tenotomies, or shortening of the muscles, or advancement with tenotomy of the opposing muscle, until he began doing exclusively simple advancements, an operation, as he thinks, which admits of accurate adjustment, and gives permanent results.

A MANUAL ON DISEASES OF THE NOSE AND THROAT.

A Guide to Diseases of the Nose and Throat, and Their Treatment. By CHARLES A. PARKER, F. R. C. S. (Edin.), Consulting Surgeon to the Throat Hospital, Golden Square, W., and LIONEL COLLEDGE, M. B., F. R. C. S., Surgeon to the Ear and Throat Department, St. George's Hospital, S. W., and to the Throat Hospital, Golden Square, W. Second Edition. London. Edwin Arnold, 1921. Pp. xv-583.

Many portions of this useful guide have been rewritten and much new matter has been added, owing to the delay in preparing the edition, caused by the war. In its present form Parker and Colledge give us an excellent manual for the instruction of the postgraduate student as well as a convenient reference handbook for the practitioner. The most instructive and practical section of the entire volume is the introductory one, dealing with methods of examination of the upper respiratory tract, the various procedures of local treatment, with numerous formulae; and the general principles and technic of internal and external operations, and of diathermy.

MERRICK.

A Chair on the Boulevard. By LEONARD MERRICK. With an Introduction by A. NEIL LYONS. New York: E. P. Dutton & Co., 1921. Pp. xiii-390.

A collection of stories with great charm. They show a bit of O. Henry, of Balzac, of De Maupassant, and yet have an individuality all their own. The boulevard and the twisting stairway of the Paris Latin Quarter are brought to the reader without the ponderousness of detailed description. Each story in the book may be depended upon to furnish an enjoyable *quart d'heure*.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

ADDRESSES ON PSYCHOANALYSIS. By J. J. PUTNAM, M. D., Emeritus Professor of Neurology, Harvard University. With a Preface by SIGMUND FREUD, M. D., LL. D. International Psychoanalytical Library, No. 1. London, Vienna and New York: The International Psycho-Analytical Press, 1921. Pp. 470.

PSYCHOANALYSIS AND THE WAR NEUROSES. By Dr. S. FERENCZI (Budapest), Dr. KARL ABRAHAM (Berlin), Dr. ERNST SIMMEL (Berlin), and Dr. ERNEST JONES (London). Introduction by Prof. SIGMUND FREUD (Vienna). The International Psychoanalytical Library, No. 2. London, Vienna and New York: The International Psycho-Analytical Press, 1921. Pp. 59.

GENERAL PATHOLOGY. An Introduction to the Study of Medicine, being a Discussion of the Development and Nature of Processes of Disease. By HORST OERTEL, Strathcona Professor of Pathology and Director of the Pathological Museum and Laboratories of McGill University and of the Royal Victoria Hospital, Montreal, Canada. New York: Paul B. Hoeber, 1921. Pp. xxi-357.

DIABETES MELLITUS. A System of Diets. Diet Table I: Starch Free Diet, Qualitative List; Diet Table II: Minimal Fat, Starch Free, Measured Diet; Diet Table III: Minimal Fat, Starch Free, Weighed Diet; Diet Table IV: Low Fat, Starch Free, Measured Diet; Diet Table V: Low Fat, Starch Free, Weighed Diet; Diet Table VI: Accessory Diet, Rich in Carbohydrates. By HERMAN O. MOSENTHAL, M. D., Assistant Professor of Medicine and Attending Physician, New York Post-Graduate Hospital and Medical School. New York: Paul B. Hoeber, 1921.

THE ASSESSMENT OF PHYSICAL FITNESS BY CORRELATION OF VITAL CAPACITY AND CERTAIN MEASUREMENTS OF THE BODY. By GEORGES DREYER, C. B. E., M. A., M. D., Fellow of Lincoln College, Professor of Pathology in the University of Oxford; Corresponding Member of the Royal Danish Academy of Letters and Sciences. In Collaboration with GEORGE FULFORD HANSON, Late Lieutenant U. S. A. Medical Corps, Air Service. With a Foreword by CHARLES H. MAYO, M. D., Rochester, Minn. New York: Paul B. Hoeber, 1921. Pp. xiv-127.

ANXIETY HYSTERIA. MODERN VIEWS ON SOME NEUROSES. By C. H. L. RIXON, M. D., M. R. C. S. Senior Neurologist, Ministry of Pensions' Neurological Hospital, Exeter, Late House Physician, Casualty Officer, and Resident Anesthetist, St. Thomas's Hospital; Captain, R. A. M. C.; Officer in Charge of Neurological Section, Reading War Hospital, and D. MATTHEW, M. C., M. B., Ch. B., Neurologist, Ministry of Pensions' Neurological Hospital, Exeter; Late House Physician, and House Surgeon, Dundee Royal Infirmary; Captain, R. A. M. C. With a Foreword by Colonel Sir A. LESLIE WEBB, K. B. E., C. B., C. M. G., etc., Director General of Medical Services, Ministry of Pensions. New York: Paul B. Hoeber, 1921. Pp. xi-124.

Practical Therapeutics

TREATMENT OF ACUTE ALIMENTARY DISTURBANCES OF INFANCY.

BY HARRY LOWENBURG, A. M., M. D.,

Philadelphia,

Pediatrist to the Mount Sinai and Jewish Hospitals.

The multiple classifications of the diarrheas of infancy, variously founded upon more or less insecure pathological, etiological, and clinical data, have provided a medley of therapeutic procedures according to the particular viewpoint adopted by their originators. Of far-reaching importance is the knowledge that rarely, except in the truly infectious types of the disease, which, except in epidemics, constitute the minor number of cases seen, do definite or lasting changes develop in the mucosa of the gut. This observation has been made in innumerable instances, to the amazement and discomfiture of painstaking observers in cases when death resulted from severe alimentary disturbances for which no explanation seemed available. Thus have become obsolete the terms gastritis, gastroenteritis, enterocolitis, and similar expressions, in so far as each respectively is intended to represent definite organic change in a particular section of the gastrointestinal mucosa and a definite symptom complex as characteristic of that section supposed to be involved. Pathology alone therefore cannot provide us with a proper index for treatment. It will be seen that the trouble lies not so much in the intestinal wall as in the intestinal contents. Clinical data likewise, i. e., a classification based upon symptoms alone, will not provide a definite basis for treatment.

Viewed etiologically, however, the situation may be more intelligently approached. Certain types of bacteria, supposedly having invaded the intestinal mucosa, were held responsible for the various forms of the condition as represented by more or less severe vomiting, the different types of diarrhea, and systemic toxemia. However, this can be true of but a limited number of cases, the infectious type already referred to, notably the Shiga bacillus variety of dysentery. The principal food elements, protein, carbohydrate and fat, producing so-called food injuries and resulting in protein intolerance, carbohydrate intolerance, fat intolerance, as represented by supposedly definite gastrointestinal symptoms ascribable to each respectively, cannot alone explain or form a basis for definite treatment. Nor can the effect of high temperature, either through its action upon the principal food, milk, or by reason of its depressing effects upon the individual, as many of these cases occur during cool weather. A combination of these elements, however, especially the first two, bacteria and food, provides the most rational explanation and points the way to treatment.

Bacteria require pabulum for their growth and development. Food provides that pabulum and the type of food will determine the preponderating type of bacteria in the intestinal flora. The disintegration of certain foods, notably fat and sugar, pro-

duce an acid medium in which only acid producing organisms will thrive. These organisms, together with certain enzymotic agents, further assist in the digestion or disintegration of these food elements. When within the limits of tolerance, this action is normal and a state of intestinal neutrality or of mild alkalinity is maintained by the digestion and disintegration of protein, which provides an alkaline medium in which many alkali producing organisms will thrive and which in turn assist, together with enzymotic agents, in the digestion of protein. Thus there exists a certain form of symbiotic activity between food and bacteria and this activity seems to be the responsible factor determining intestinal normality or abnormality. Fat and sugar determine intestinal acidity; protein determines intestinal alkalinity. A correct balance between the three means normality and it is readily conceivable how by means of proper food manipulation the actions of the bowels may be controlled. If either excessive acidity or excessive alkalinity persists over too long a time diarrhea and systemic disturbance will ensue as a result of irritation of the intestinal mucosa. The bowel runs exactly as the nose runs when the Schneiderian membrane is irritated by snuff, for instance. Thus it becomes clear that the exciting factor lies not within the intestinal wall but within the intestinal contents as previously stated and it seems logical to assume that by means of an intelligent application of diet we possess the most effective means, not only of preventing but of curing the acute alimentary disturbances. This is borne out clinically. However, one may not speak accurately of a protein disturbance, a fat disturbance, or a sugar disturbance, by reason of the mere presence of any excess of any particular food element in the stool. Anything that increases peristalsis to the point of causing diarrhea interferes with the digestion of all the food elements and hurries them through the intestinal canal. Hence, if sugar happens to cause the diarrhea there is no good reason to expect that the stools will not contain an excess of undigested protein and fat curds and oil globules. The same effect would result from mixing a purgative with the food and yet it would be manifestly wrong to regard the appearance of curds as confirmatory of the baneful effect of protein or the fat of the food as the case may be.

Diagnostically and therapeutically, therefore, more information is obtained from a study of the reaction of the stool than from its gross and microscopic appearance and from a careful history of the case, for after all the matter of food tolerance is a matter of individual resistance and is not determined by a fixed academic percentage of a particular ingredient. Excessive alkalinity would indicate that cure would be accomplished by the withdrawal of protein and the feeding of fat and sugar in tolerable amounts. Excessive acidity, by far the more common occurrence in diarrhea, indicates the withdrawal of fat and sugar from the diet and the feed-

ing of large amounts of protein in digestible form. Inasmuch, however, as anything which would cause diarrhea impairs the functional activity of the gut, the first requisite of treatment, irrespective of the causative factor, would be the withdrawal of all food in order to rest the bowel and thus increase its digestive functions, or, in other words, its tolerance for any food element.

TREATMENT.

As far as treatment goes, from the foregoing, therefore, diarrhea may conveniently be roughly classified as noninfections—that dependent on food and bacteria within the gut, and the infectious—that wherein the bacteria have invaded the intestinal wall and are responsible for inflammation and ulceration. In order to meet the indications of the more common variety or the noninfectious type—that dependent upon fat and sugar intolerance, Finkelstein has provided us with two fundamental procedures, a, hunger period of twenty-four to forty-eight hours and, b, the use of comminuted cow curd as represented by Eiweissmilch (albumin milk—protein milk), which is fat and sugar poor and protein rich and in which the protein exists in finely comminuted curds.

The question of purgation must be decided in each individual case. If the infant is toxic, as evidenced by extremely high temperature, then swift purgation is indicated. Calomel is too slow and should not be employed unless vomiting, which does not yield to a single lavage, is present, when the drug should be placed dry upon the tongue in doses one tenth to one twentieth of a grain for ten doses every ten to fifteen minutes. During this time no fluid or food is given by mouth. Half an hour after the last dose half an ounce of castor oil is administered. If vomiting is absent or yields to a single lavage, calomel is omitted and castor oil is administered immediately. The majority of infants, however, do well without initial purgation if the temperature is not high. Diarrhea for the first twenty-four hours may be regarded as a benign process, provided no food is given. The bowel simply empties itself of irritating material.

Whether purgation is employed or otherwise the next step in the management of these cases is probably the most important of all and must be strictly enforced. This consists of a hunger period to which reference has just been made and which should last from twenty-four to forty-eight hours, depending upon the severity of the symptoms; usually twenty-four hours is sufficient. During this time absolutely no food of any character is allowed. This cannot be too strongly impressed upon the person in charge of the case. Weak tea is administered freely. It is made in the usual way from ordinary tea leaves and is sweetened with one grain of saccharin to the quart. It may be administered cool or at room temperature. The infant may take as much of it as it will and its use is not contraindicated by vomiting should this be continued, after lavage or the calomel course. Even after feeding is started the tea may be administered between feedings simply as a drink. During the hunger period saccharated tea serves to provide fluid, which is all important in combating acidosis, and it is also

slightly astringent. During the tea feeding period or immediately following it and continued over a more or less indefinite period of the illness, i. e., until the stools become thick and constipated, the following is administered every three hours in teaspoonful doses:

Calcii carbonatis (cretæ preparati).....	5iv
Fuller's earth	5ii
Tr. kino	fl. 5iv
Oil anise	ʒiii
Aquæ des., q s. ad.....	fl. ʒiii
Saccharin	gr. 1/10

The purpose of the calcium carbonate is to hasten intestinal alkalinity. The fuller's earth is a thickening, alkalizing and astringent agent. Kino is a powerful astringent. Oil of anise is carminative and of pleasant flavor and the saccharin sweetens. This combination has proved eminently satisfactory and is a decided improvement upon the old chalk mixture since the latter is too rich in sugar, which at this stage of the treatment should be withheld.

Aside from this no other medication is employed unless clearly indicated, and this rarely happens in the noninfectious type of diarrhea. Excessive peristalsis and restlessness may be controlled by small hypodermic injections of morphine sulphate (one eightieth to one twentieth of a grain), repeated if needed at six hour intervals. I have also experienced excellent quieting and anticolicky effect from small doses (one sixteenth to one half of a grain) of luminal. Where there have been repeated relapses, the result of mismanagement, and the infant appears dehydrated, the intraperitoneal injection of normal saline or the same given by hypodermoclysis or intravenously by fontanelle (longitudinal sinus route) or a five per cent. solution of sterile glucose solution—one sixtieth of the body weight, are all useful lifesaving measures, as is also hydrotherapy (bathing) in general.

Irrigations.—These need not be employed unless blood is present in the stool, when once or twice daily a pint or more of one half of one per cent. solution of tannic acid, temperature 100° F., may be allowed to run in and out of the bowel. It seems to have an excellent effect in causing the blood to disappear.

Hydrotherapy.—High temperature and restlessness, if not controlled by the hunger period and purgation, are best influenced by the gradually cooled bath. The temperature is started at 100° F. and gradually cooled to 80° F. while the patient remains immersed. The effect is usually prompt and persists over a period of three to four hours, when it may be advantageously repeated if necessary. This measure failing to control restlessness, however, recourse may be had to morphine or luminal, as just stated.

Feeding.—This logically follows the preliminary treatment by starvation and tea. If we believe that the majority of these cases of diarrhea depend upon fermentation of fat and sugar, which serve as pabula for the acid producing bacteria, as evidenced by the reaction of the stools to litmus paper, then these substances must be eliminated from the diet for no antiseptic possesses the power to destroy or change the intestinal bacterial flora as well as the food pabulum in which these bacteria find them-

selves. They will disappear if their source of life is destroyed or withheld. This is the correct philosophy which underlies a correct conception of the dietetic treatment of these cases. Hence we must provide aliment upon which only alkalinizing microorganisms will thrive. The end products of the enzymotic and bacterial digestion of this agent must tend to produce intestinal alkalinity or at least intestinal neutrality. Such a substance is protein.

Ordinary cow curd, however, is thick and tough and indigestible to a high degree. This may be influenced favorably by boiling, predigestion, cereal decoctions, dilution, citrate of soda or best by mechanical comminution, as found in buttermilk or the albumin milk of Finkelstein. The latter is an excellent therapeutic agent in controlling the diarrheas of infancy. Great difficulty, however, has been experienced in making it in the home and it is not commercially available in liquid form in America. Stoeltzner, of Halle, has suggested a dried preparation of Finkelstein's milk which is known as larosan and which is an agent of inestimable value in the management of the acid diarrheas of infancy. Larosan consists of chemically pure casein, precipitated from milk, and which has been rendered soluble in hot milk by exact neutralization with calcium hydroxide and subsequent evaporation to dryness; it is therefore a soluble calcium caseinate. It is a white powder of light consistency and is really an evaporated or dried albumin milk. My method of procedure, therefore, following the hunger period, is to start the infant on a weak formula as follows:

Skim milk 5 oz.
 Water15 oz.
 Salta pinch
 Larosan1 to 2 packages
 (These packages contain two thirds of an ounce of the dried powder.)
 Unsweetened cocoa2 teaspoonfuls
 Saccharin1 gr.

The water and milk and salt are mixed together and the larosan is added slowly, stirring to prevent the formation of lumps. Strain, bring to boiling point, stir, and while hot add the cocoa without lumps. Strain and whip with an egg beater till cool and add sufficient cool boiled water to bring the total bulk up to twenty ounces. Feed from two to six or more ounces every three hours according to the age and appetite of the infant. The mixture is of course warmed before feeding. If a sediment appears it does no harm. It is only necessary to remember to shake the container thoroughly before pouring the necessary ration. The preparation may be made without cocoa but in my experience the use of this agent has proved to be of extreme value. It is nutritious as well as astringent and therefore constipating and further adds materially to the taste of the mixture and most infants take to it readily. The preparation, however, without the cocoa is not unpleasant to the taste if properly sweetened, and even in cases where it appears desirable to withhold milk entirely, may be used simply by diluting it with water and adding some sweetening agent.

Following the use of this mixture, together with the chalk, fuller's earth and kino mixture, it may be predicted with almost mathematical accuracy that within twenty-four to forty-eight hours the infant

will pass a thick brown, constipated stool. If the cocoa has been omitted the stool will be yellow. The reaction will be alkaline.

It is necessary, however, to proceed further with the nourishment because the mixture above ordered is not sufficiently strong to nourish. Hence an ounce of milk replaces an ounce of water from day to day until a mixture is reached that appears sufficient at least to maintain tissue balance. While the larosan and cocoa mixtures are not regarded as permanent foods, nevertheless the error is usually made in removing them too soon. They should be used until a certain feeling of surety prevails that relapses will not occur. After the stools have become thick and brown or thick and yellow, if cocoa has not been employed, carbohydrate is cautiously added. My own preference is for cane sugar as experience and habit of years have convinced me that it is as serviceable and as least likely to disagree as any of the sugars. This being so its accessibility is an additional reason for its use. At first one half of one per cent. of the total volume of formula is employed and the amount is gradually increased until three or four or five per cent. is reached. More than this is neither necessary nor safe. For those who so prefer, milk sugar or malt sugar in its various forms as found on the market may be substituted. A few formulas follow as illustrative of the method of procedure. Not any of these are intended as a criterion for use at any particular age. This must be decided at the time according to the infant's appetite and digestive powers and its general condition. The fundamental idea is to start the milk weak and then gradually work it up. As the carbohydrate is increased the saccharine is gradually omitted.

Skim milk 6 oz.
 Water14 oz.
 Saltpinch
 Larosan1 to 2 packages
 Saccharin1 gr.
 Cocoa (unsweetened)2 teaspoonfuls

Skim milk 7 oz.
 Water13 oz.
 Saltpinch
 Larosan1 to 1½ packages
 Saccharin1 gr.
 Sugar1 teaspoonful
 Unsweetened cocoa2 teaspoonfuls

Skim milk 8 oz.
 Water12 oz.
 Saltpinch
 Larosan1 package
 Saccharin½ gr.
 Sugar2 teaspoonfuls
 Unsweetened cocoa2 teaspoonfuls

Skim milk 9 oz.
 Water11 oz.
 Saltpinch
 Larosan1 package
 Saccharin½ gr.
 Sugar3 to 4 teaspoonfuls
 Unsweetened cocoa2 teaspoonfuls

Skim milk10 oz.
 Water10 oz.
 Saltpinch
 Larosan1 package
 Saccharinomitted
 Sugar5 to 6 teaspoonfuls
 Unsweetened cocoa2 teaspoonfuls

Skim milk	10 oz.
Water	10 oz.
Salt	pinch
Larosan	½ package
Sugar5 to 7 teaspoonfuls
Unsweetened cocoa	1 teaspoonful

And so the method proceeds until a strength suitable to the individual is reached. This may be a partially diluted or undiluted skim milk; diluted partly skim milk, or diluted whole milk or whole milk. By this method of gradual increase of strength, meanwhile continuing the larosan and cocoa, the general weight is not only maintained but an actual increase may occur. This is particularly so if well cooked cereal, such as farina or cream of wheat, is added to the diet, first once, then twice a day, just preceding a bottle feeding. Small amounts are first employed as one to two teaspoonfuls, and these are gradually increased to two to three table-spoonfuls. The cereal after cooking in water in a double boiler for two hours is served with a pinch of salt, a sprinkle of sugar and a half an ounce or so of milk, and the same of water and brought to what would be the boiling point (too thick to boil) a second time. If the infant is beyond six or seven months and not too feeble, the gradual addition of mashed baked sieved potato with some mashed sieved greens, such as spinach, should be started once daily—preferably around the noon hour.

There now develops in each case a time when the albumin milk feeding is no longer needed and the larosan and cocoa are omitted from the formula. When to make this change to a simple formula of boiled diluted whole, or diluted skimmed or partly skimmed milk, must be decided for each individual case. Certain criteria are of value in making this decision and the most reliable is the condition of the stool. If this is thick and mushy and free from blood and mucus, the larosan and cocoa may be omitted. Undue haste, however, in doing this or in increasing the fat and sugar content of the milk mixture, will lead to a relapse. Relapses are treated exactly as original attacks including the use of a hunger period and tea feeding as previously described. It is worth repeating that the weak saccharated tea may be continued throughout the course of the case, being used simply as a drink between feeds. Medication with the mixture of calcium carbonate, fuller's earth, and the other substances, should also be continued for several days throughout the course of the case, in gradually lengthening intervals, but care should be exercised not to discontinue it too soon.

After the attack, great care is needed to preclude relapses by preventing the influence of the factors which were responsible for the first attack. Milk should be boiled, overfeeding should be avoided, rich milks and cream should be restricted and great care exercised in feeding sugar. The depressing effects of external heat must be combated if summer prevail. Two drops of tincture of nux vomica in a little water and given before feeding will be useful.

INFECTIOUS DIARRHEA.

The general management of these cases differs very little from those of the noninfectious type, except that one must proceed more cautiously in in-

roducing milk of any kind in the diet. The results of treatment are by no means as good and many infants succumb to the toxic effects and to dehydration and demineralization. Sera have given very little encouragement for their use. An attempt should be made to discover the dysentery organism. The free use of water and the intraperitoneal injection of saline and of tannic acid irrigations may be lifesaving. Alkalis, such as potassium citrate and bicarbonate of soda, in large doses by the mouth, are often useful in combating acidosis. Morphine, brandy, digitalis, Siberian musk and camphor may, each or all, be useful when indications for such remedies arise.

ILLUSTRATIVE CASES.

CASE I.—Baby H., ten months old, breastfed; had been ill six weeks when first seen. Birth weight was nine pounds; weight at beginning of illness twenty pounds; weight after six weeks of illness, fifteen pounds. Symptoms began with vomiting. Whole raw milk had been given, and fever and diarrhea were present. The patient had received during six weeks of treatment various proprietary foods, purgatives and homeopathic remedies. The infant was wasted, irritable and toxic; temperature was 103° F.; vomiting; fifteen and more stools daily containing mucus, undigested milk, and some blood, reaction acid. Treatment for the first twenty-four hours: hunger period with saccharated tea, hydrotherapy, simple fever mixture, colonic irrigations with one per cent. tannic acid solution; temperature 100° F. morning and evening. On the second day, tea was continued as a drink, and one dram of the diarrhea mixture, as detailed above, was administered every three hours. Tannic acid irrigations were continued; temperature 99° F., vomiting ceased, bowels had not moved. The following preparation was ordered:

Skim milk	10 oz.
Water	20 oz.
Larosan	3 packages
Salt	a pinch
Saccharin1 gr.
Cocoa (unsweetened)	3 teaspoonfuls

Fed six ounces every three hours.

Third day, temperature 99° F., no vomiting; bowels moved twice, thick chocolate stools, some mucus, no blood. Tea was continued as a drink. Similar treatment was continued for two weeks, gradually increasing the strength of the formula. Diarrhea mixture and saccharated tea were continued during this time. Irrigations were stopped after one week. Carbohydrate was added gradually to the diet. Larosan and cocoa were stopped at this time and feeding continued with the following:

Skim milk	20 oz.
Water	10 oz.
Cane sugar	1 oz.

Powdered flour ball with pancreatin and bicarbonate of soda (one ounce of the former and five grains and fifteen grains, respectively, of the latter). These substances added to the formula at 100° F. for fifteen minutes, and then brought to boil. Seven ounces every three hours.

In addition cereal was fed twice daily and once daily mashed baked sieved potato and mashed sieved spinach. There was some tympany so two drops of tincture of nux vomica and two drops of tincture of belladonna, four times a day, were ordered.

Bowels were normal, moved twice daily, free of mucus and blood. Infant was contented, weight sixteen pounds six ounces. At the present writing it weighs twenty-two pounds, has cut four teeth without disturbance, and is walking at thirteen months. It is receiving whole boiled milk, cereal, egg, vegetables and minced chicken and beef and baked apple.

CASE II.—W. B., male, five months, September 23, 1920. Birth weight eight pounds twelve ounces, present weight nine pounds twelve ounces. It was breast fed for one day. It did not thrive; suffered from diarrhea. It was now on barley water and milk mixture. Treatment consisted of a hunger period, saccharated tea, and the diarrhea mixture.

Skim milk 7.5 oz.
 Water 22.5 oz.
 Salt pinch
 Cane sugar ½ oz.
 Larosan 2 packages
 Cocoa 3 teaspoonfuls

Six ounces every three hours.

On September 25, 1920, its weight was nine pounds nine ounces; bowel movement better. Ordered two tablespoonfuls of cereal in the morning and the evening just preceding the following formula:

Skim milk 10 oz.
 Water 20 oz.
 Salt pinch
 Sugar ¾ oz.
 Larosan 2 packages
 Cocoa 2 teaspoonfuls

On September 27th the infant's weight was nine pounds ten ounces. Condition continued the same. Bowel movements were thick and brown.

On September 29th the weight was ten pounds two ounces. Bowel movements were thick and brown, two daily. The following mixture was ordered:

Skim milk 11 oz.
 Water 19 oz.
 Salt pinch
 Sugar ¾ oz.

Larosan and cocoa reduced to one half amount.

This method of gradually reducing the cocoa and larosan was continued with increase of skim milk and decrease of diluent and gradual increase of sugar for about two weeks when a change was made to a simple milk formula with cereal fed twice a day. Infant improved in weight and general condition. On November 15, 1920, it weighed sixteen pounds and beside cereal, egg, mashed potato and spinach it was taking the following formula:

Skim milk 24 oz.
 Water 6 oz.
 Salt pinch
 Sugar 1½ oz.

Eight ounces every three hours.

CASE III.—A. E., four months old on September 9, 1920. Birth weight was seven pounds five ounces, present weight ten pounds eight ounces. Was breastfed for sixteen days; now getting boiled water and milk and Robinson's barley flour. Complaint—diarrhea, fifteen movements daily; buttocks excoriated, no vomiting, no elevation in temperature, stools green, mucus, curds, acid. Treatment was started with a hunger period, saccharated tea, diarrhea mixture,

and after twenty-four hours the following mixture:

Skim milk 5 oz.
 Water 15 oz.
 Salt pinch
 Saccharin 1 gr.
 Larosan 1 package
 Cocoa 2 teaspoonfuls

On September 11, 1920, the infant was constipated, bowel movements dark brown, three daily.

CASE IV.—L. G., female, fourteen months. Birth weight eight pounds eight ounces, present weight twenty pounds. Complaint, diarrhea for one week, with ten to twelve watery acid movements daily, buttocks excoriated, temperature normal. Saccharated tea was given for twenty-four hours, followed by diarrhea mixture. No movement appeared after hunger period was instituted until thirty-six hours later.

Skim milk 20 oz.
 Water 20 oz.
 Salt pinch
 Larosan 2 packages
 Saccharin 1 gr.

The next bowel movement was thick, yellow, constipated smooth, alkaline.

In all there are records of some forty-five to fifty office cases wherein this method of treatment was followed and in all wherein directions were carried out the results were good. In a few instances the infants refused the mixture. Here the addition of cocoa usually made it acceptable, although in two or three instances, even after persistence, it was refused. In such cases reliance was placed upon saccharin sweetened skim milk mixtures thickened with powdered arrowroot (two drams to the pint of formula) or to the same mixtures to which powdered flour ball and pancreatin with bicarbonate of soda had been added. Space forbids further details of cases treated. Those described are sufficient to make clear the method pursued.

In the infectious type of the disease, except in true dysentery, we possess no special therapy and must rely upon the measures enumerated. Sera are disappointing although good seems to have followed the use of antidysenteric and of antistreptococcic serum in a few cases. Emetin should also be employed where bloody mucous stools persist. In these cases high temperature and toxemia must be vigorously combated. Cold bathing is always dangerous in infants.

SUMMARY.

1. Purgative: To be employed if temperature and toxemia are pronounced. Castor oil, or calomel, if vomiting does not yield to a single lavage, to be followed by castor oil.

2. Hydrotherapy.

3. Hunger period for twenty-four to forty-eight hours. During this time give freely of saccharated tea (one grain to a quart) regardless of vomiting and continue same throughout treatment as a drink.

4. Feeding of diluted skim milk mixture sweetened with saccharin (one grain to twenty ounces) and containing larosan with or without unsweetened cocoa. The skim milk and the larosan mixture may be replaced by Finkelstein's eiweissmilch if this is available. Carbohydrate is gradually added, preferably cane sugar, and strength of formula otherwise

gradually increased. Larosan cocoa and sugar gradually are reduced as mixture becomes stronger. Formula may then be boiled with arrowroot or flour ball, pancreatin and bicarbonate of soda may be added. Cereals and vegetables (comminuted) are gradually added.

5. Diarrhea mixture continued throughout treatment.

6. Potassium citrate in large dose if acidosis is marked.

7. Irrigations of one half to one per cent. tannic acid solution if stools contain blood.

8. Demineralization and dehydration combated by intraperitoneal injection of saline, or intravenous injection of saline, glucose, or alkaline solutions if acidosis is marked.

2011 CHESTNUT STREET.

Treatment of Ununited Fractures.—M. S. Henderson (*Annals of Surgery*, April, 1921) gives the following résumé: As a result of our experience in the treatment of ununited fractures we believe that the bone graft is primarily the method of choice, but there are certain conditions in which it is probably not the best method. Frequently in operations on certain ununited fractures of the femur with much fibrous tissue and abundant callus, in which bleeding is very free and cannot be controlled absolutely, we have found it better to use metal or beef bone plates, which are more easily applied than autogenous bone grafts. Beef bone plates and screws are not irritating and have sufficient strength to stand the strain. In treating ununited fractures of the tibia the inlay graft is probably the method of choice; this, like all bone grafts, should be held firmly in place by the aid of beef bone screws. In the femur and humerus, and in the radius and ulna, we prefer the massive bone graft which permits the approximation of the cancellous tissue of the graft and of the fragments.

Treatment of Fracture of the Forearm in Children.—Jacob Grossman (*Journal of Orthopedic Surgery*, May, 1921) concludes as follows: 1. Where, for any length of time, infants and children refuse to use their forearms, after having sustained an injury, fracture should be suspected. 2. Colles's fracture occurs rarely in infants and children. 3. Fracture may be present, even though the cardinal signs of fracture are lacking. These fractures are usually of the subperiosteal variety. Pencil tenderness is the diagnostic sign. 4. Epiphyseal separation of the lower end of the radius should be looked for in all cases with injured forearm. It occurs often enough to be considered. 5. Plaster of Paris bandages are by far more efficient than splints and should be given the preference in the treatment of fractures. 6. Proper immobilization is as important as proper reduction in obtaining a successful issue in the treatment of fractures. 7. Shorter periods of immobilization, early massage and passive movements should be employed in children. 8. A pad between the shafts of the fractured bones, as recommended by many, for the purpose of preventing fusion of the fractures, is unnecessary as it could not separate the bone ends without exerting injurious pressure upon the circulation.

Treatment of Scoliosis.—S. Kleinberg (*Surgery, Gynecology and Obstetrics*, April, 1921) asserts that the most effective means of recognizing scoliosis early is by regular frequent examinations of the naked backs of all school children. Corrective treatment should be instituted as soon as the curvature of the spine is discovered. Treatment should be carried on uninterruptedly for years until improvement has been obtained and until such time as will reasonably assure arrest of the deformity. Treatment with the spine in extension is at present the best form of treatment for it enables us to arrest the progress of the deformity and in many instances to reduce the curvature. It is the least uncomfortable treatment and does not cause malformation of the chest. The essential feature of the treatment is keeping the patient in a position that is opposite to that of the deformity. During change of jackets there must be no opportunity for relapse of the deformity.

Abortive Serum Treatment of Typhoid Fever. G. Etienne (*Paris médical*, March 19, 1921) states that Rodet's antityphoid serum is capable of aborting typhoid fever in a large proportion of cases when the treatment is begun between the eighth and tenth days of the disease. The fastigium is done away with and the period of decline usually begins between the tenth and twelfth days of the disease. This result was obtained in fifteen out of twenty-three cases thus treated. In the remaining eight cases the result was interfered with either through failure of the temperature and general condition to show consentaneous improvement, through secondary infection, or through actual failure of the treatment to cause anything more than an attenuation of the typhoid manifestations. However severe the typhoid case may be at the start, it generally follows the mild course of typhoid in a vaccinated individual when the serum is administered before the tenth day.

Ultimate Results of Laryngectomy for Cancer of the Larynx.—E. J. Moure (*Bulletin de l'Académie de médecine*, March 1, 1921) maintains that if cases of cancer of the larynx could be subjected to early operation, permanent cure would be the rule in this disorder, upon which neither radium nor the x rays have as yet seemed to have any hold. Out of thirty-one cases dealt with surgically by the author, two patients died soon after the operation, including one with an abscessed lung. Twelve died in six months to a year from local recurrence. Four more died two or three years after the operation, from intercurrent disorders. Eleven appear to have been definitely cured, remaining well for periods of from one to nine years after the operation. The two other cases were lost sight of. In general, it seems that if recurrence has not taken place at the end of one year, either locally or in the cervical glands, the case may be considered cured. Laryngectomy may now be looked upon as a relatively mild operation which gives very useful results if performed under favorable circumstance and in due time. The author has improved the operation of late by making only a single broad flap, which gives better exposure of the excised organ and facilitates subsequent plastic surgery.

X Ray Treatment in Acute Dyspnea the Result of Tracheobronchial Glandular Enlargement.—D'Elsnitz and Carcopino (*Bulletins et mémoires de la Société médicale des Hôpitaux de Paris*, March 10, 1921) report the case of a child aged three years who, upon admission to a hospital, was at once isolated for diphtheria and given antitoxin, having been thought suffering from laryngeal diphtheria. The history obtained was that the child, apparently well the preceding evening, had waked up in the night with severe difficulty in breathing. Examination showed her face somewhat cyanosed, with marked dyspnea and infrasternal depression during inspiration, hoarse voice, temperature 39° C., pulse very frequent, throat slightly reddened, breath sounds reduced especially on one side, and absence of abnormal thymic dullness. Immediate x ray examination revealed a marked glandular shadow masking the entire middle portion of the retrocardiac space and extending more distinctly toward the right; there was no thymic shadow. The x rays were then used for therapeutic purposes over the chest for fifteen minutes; this caused immediate betterment of breathing, and the next day the child seemed well and remained so thereafter. The conclusion reached from this and other cases is that while the x rays cannot as yet be said to exert a selective action in chronic enlargement of mediastinal glands, they constitute a useful emergency treatment in acute cases with pronounced dyspnea.

Incontinence of Urine in Childhood.—Charles E. Sundell (*Practitioner*, April, 1921) says that it is necessary to investigate every case of enuresis very fully, and to take into account all the factors which may have a bearing upon it. The most successful line of treatment is a triple one: 1. Deal with the associated conditions, if they are present; 2, build up the health of the child with a special regard for its nervous balance; and 3, form and confirm a habit of recognition of the bladder's desire to empty itself. The method of treatment upon the first line has been indicated—it is at best subsidiary. The second line of treatment includes attention to the whole nutrition, habits of work, play and rest, and an estimation of the general health of the child. Arsenic in small doses is the most useful drug, and can be combined with strychnine with advantage. Attempts to influence the lumbosacral cord directly by intrathecal injections of normal saline are a crude procedure; there is no real evidence that the spinal centre is at fault in these cases, and this line of treatment is unjustifiable. The main effort in the campaign against enuresis must be directed to the brain and consciousness, and most important of all is the cordial, continuous, and self-sacrificing cooperation of the mother or nurse. Under similar conditions of life and activity during the waking hours, and with similar amounts of food and fluid in the diet from day to day, it will be found that enuresis occurs at a fairly constant time during the night. In order to determine this hour the mother will have to sacrifice her sleep for several nights, look at the child every half hour, and record the time at which bedwetting occurs. By this means a timetable of enuresis for the individual child can be compiled, and it will be found that

this remains constant. When this timetable is once established, the rest is easy. The child must be roused a quarter of an hour before each bladder emptying is due. Habits are very easily formed in childhood, and treatment on these lines will quickly ensure that the child wakes spontaneously, and by a judicious system of rewards he can be trained to empty his bladder in the proper manner. This line of treatment is most successful, but it calls for two forms of sacrifice upon the part of the mother: first, complete supervision during the day so as to render each day's routine as nearly like its predecessor as possible; and second, the greater sacrifice of sleep for several nights in succession.

Colic in the Nursing Infant.—T. Wood Clarke (*New York State Journal of Medicine*, April, 1921) is sceptical of the frequent diagnosis of colic in the nursing infant. He believes that there are three conditions which produce symptoms commonly attributed to colic. These are hunger, otitis media, and temper. There is, of course, such a thing as true colic in infancy; the irregularly fed infant, the infant fed on patent foods, or the infant getting too much fat or sugar may have true colic. Appendicitis, peritonitis or intestinal obstruction will give a real entity, but in such cases the baby looks and is ill. The point to be brought out is that in the properly breastfed infant, and the decently fed bottle baby, the symptom complex diagnosed by the family and treated by the physician as colic, if carefully studied, will be found in the vast majority of cases to be in no way associated with intestinal spasms but to be due to hunger, earache, or temper.

Clinical Study of Tuberculosis in Children.—Abraham Levinson (*Medical Record*, May 7, 1921) summarizes his study of three hundred children, most of whom had come in contact with tuberculous people. Of these children one hundred and forty-one reacted positively to the von Pirquet test, eighty-three were negative and seventy-six were still pending on diagnosis. Of the one hundred and forty-one positive cases ninety per cent. had only a latent infection, and in only three cases was there active pulmonary tuberculosis. In ninety-eight per cent. of the latent cases the patients presented no subjective symptoms, and in ninety per cent. the patients were from four to eight per cent. under weight. Long eyelashes and visible veins over the chest were present in the greatest number of children with latent tuberculosis. Seventy-five per cent. of the positive cases showed hilus dullness and whispered bronchophony to the seventh dorsal vertebra. The x ray usually confirmed the hilus dullness by showing a shadow over the hilus, and often calcified spots in the substance of the lungs, and radiating toward the apex. The Eustace Smith sign of venous hum over the aortic region was very infrequent in this series. Tuberculin tests, when positive, should establish a diagnosis of the presence of tuberculosis in children. The classification of the type of infection must be made by the subjective and objective symptoms and by the x ray findings. Latent tuberculosis requires no active treatment. All children who have been in contact with a tuberculous individual should be under observation in order to establish the diagnosis and institute treatment.

Obituary.

WALLACE C. ABBOTT, M. D.,
of Chicago.

Dr. Wallace Calvin Abbott, who died at his home, 4605 N. Hermitage Avenue, Chicago, July 4, 1921, was born in Bridgewater, Vermont, October 12, 1857. His early education was obtained at the State Normal School, Randolph, Vt., the St. Johnsbury Academy, St. Johnsbury, Vt., and Dartmouth College, Hanover, N. H. Coming west, he worked his way through the University of Michigan, winning his degree of Doctor of Medicine in 1885. The following year he engaged in the practice of medicine in Chicago, building up a large practice on the North Side and winning many friends. It was during this time that Dr. Abbott established the Abbott Alkaloidal Company, now known as the Abbott Laboratories, of which firm he was president continuously from the time of its establishment until his death.

For several years previous to his decease, Dr. Abbott had been in ill health. Anticipating his active retirement from the large and successful business which he had founded, he placed the conduct of the Abbott Laboratories largely in the hands of his older employees, under a generous cooperative reorganization plan on which it has been operating for more than two years.

Dr. Abbott was a man of broad vision and great energy. He was an organizer of rare ability, warmhearted and beloved by his employees, business associates and hundreds whom he had befriended. He was a pioneer in the field of alkaloidal medication. He labored incessantly through his writings, and personal contact with thousands of physicians, to bring about a more careful study of the patient, and the treatment of separate symptoms as they

developed, as contrasted with the older method of treating by disease names only. His influence upon the medical profession in this respect has been profound.

Dr. Abbott was coauthor, with Dr. William F. Waugh, of several medical books, including *The Practice of Medicine* and *Positive Therapeutics*. He was, also, editor in chief of *The American Journal of Clinical Medicine*, now in its twenty-eighth year. For the past five years he had encouraged extensive research work along the line of new medicinal chemicals. As a result, a number of the remedies, formerly made only in Europe, are now manufactured by the Abbott Laboratories.

Dr. Abbott was a member of the Ravenswood Methodist Church, the American Medical Association, the Illinois Medical Society, the Chicago Medical Society, the Medical Editors' Association, American Drug Manufacturers' Association, American Pharmaceutical Manufacturers' Association, Ravenswood Lodge 777, F. & A. M., the Oriental Consistory and the Shrine.

Letters to the Editors.

PROHIBITION AND OTHER THINGS.

To the Editor: CANANDAIGUA, N. Y., July 8, 1921.

On looking over the Endocrinology Number of March 6th a reader must be impressed with the remarkable collection of articles relating to that interesting aspect of medicine that you have brought together in this great number, and when he considers the large amount of valuable material you have presented in the pages of the Journal in previous numbers he will cordially agree with the editors that you are rendering a distinct service to the medical profession in publishing these important papers by the masters of their respective fields.

The editorial article entitled Reformer or Idealist in the same number is an admirable crystallization of a number of ideas which I think most physicians must have entertained in the past few years, but in my judgment the force of the article is lost when you make the unfortunate comparison of the suppression of public prostitution with the suppression of the public manufacture and sale of alcoholic liquors or beverages. The similarity in the effects is imaginary, not real. You arouse only a smile in the reader's mind when you insinuate that more alcoholic liquor is consumed now than was consumed before prohibition and that prohibition has driven vast numbers of previously sober citizens to drink. It must have been a very hot, dry day when you banged that out of your typewriter! If you feel so badly about the difficulty of getting a drink why not go out and whip a couple of policemen or something? Surely it is a childish thing to insinuate that the hated 18th Amendment has made fools of a lot of ordinarily cautious, sensible folks. Perhaps you cannot see it now, but you editors (newspaper and periodical) are making plain humor in your puny efforts to oppose by every possible schoolgirl argument the enforcement of the prohibition law.

The Predisposing Factor in Diphtheria

By BELA SCHICK, M. D.,

Vienna,

Professor of Diseases of Children, University of Vienna; First Assistant to Professor Von Pirquet.

The discovery of the diphtheria bacillus has brought about a fundamental change in our methods of diagnosis of this affection. While the clinical picture furnished the only means of identification in the past, we now insist upon a certain demonstration of the specific organism. This method has enabled us to recognize mild attacks, which formerly would have been overlooked or misinterpreted. Thus, scientific precision in the diagnosis of diphtheria—the aim of many researches—appeared to have become a practical reality. Bacteriologists laid down the rule that diphtheria was present whenever the bacilli were found, and that, on the other hand, there could be no diphtheria without the organism. While the latter view has been amply corroborated, the former requires certain modifications. It did not seem surprising that the causative organisms could be demonstrated in the throat of patients who had already recovered from the disease. Thus seventy-five per cent. of the patients harbor them in a state of varying virulence up to three weeks, while in two per cent. they were found after more than ninety days.

However, confusion arose when typical Klebs-Loeffler bacilli were encountered in the mucosa of the nose and throat of healthy persons, who had never suffered from diphtheria. This finding naturally caused some alarm, since it was thought at the time that the causative organism was of itself sufficient to provoke a typical attack of the disease. The presence of the diphtheria bacillus in healthy throats was cited as the basis for an attack on the accepted etiological factors of diphtheria by those who are ever ready to place obstacles in the path of scientific progress. Little did they realize that the discovery of so-called carriers was destined to enrich our knowledge of the fundamental nature of infectious diseases. These carriers have revealed the full significance of resistance of the body to infection; they afford a daily demonstration of the fact that the diphtheria bacillus is unable to attack his host unless the individual is predisposed to the infection.

It is instructive and interesting to note that man alone is susceptible to diphtheria, though the organ-

isms have a well nigh ubiquitous distribution throughout the animal kingdom. Even the guinea-pig, the classical subject of animal experiment, never becomes a victim of the disease under natural conditions, in spite of the fact that it is not immune to the effects of diphtheritic toxins, but, on the contrary, reacts strongly against them. It has, indeed, been possible to produce the affection in animals like guineapigs and rabbits, but the lesions resemble those seen in man only in certain respects, and one of the outstanding characteristics, the formation of a membrane, appears to be restricted to man.

Numerous investigations have furnished reasons for the belief that carriers acquire the organisms by direct contact with other carriers or with persons actually suffering from diphtheria. Naturally, the question arises, why only a comparatively limited number of individuals, in fact chiefly children between the ages of one and five, fall victims to the infection, while in the vast majority of the population the presence of the bacilli has no apparent consequences? Shortly after the Klebs-Loeffler bacilli had been identified as the causative organisms of diphtheria, it was demonstrated that antitoxic substances existed both in adults and in infants. These observations led to the formulation of the axiom that susceptibility to diphtheria was caused through lack of specific antibodies. Since that time it has been confirmed repeatedly that these antibodies are absent in children suffering from diphtheria.

On the other hand, the important fact has crystallized that diphtheria cannot occur in individuals possessing protective bodies. Examinations on a large scale only became possible after a way had been discovered of testing for the presence of antibodies by means of the intradermal injection of small quantities of toxin, namely, one fiftieth of the minimum lethal dose for a guineapig weighing 250 grams. The following figures are the results of extensive animal experiments carried out by Groer and Kassowitz at the Vienna Children's Clinic. If the skin shows no reaction to the injection, the result is negative. In positive cases a sharply defined spot of erythema is noticed with an area of infiltration possessing a diameter of ten to thirty

mm. A negative result not only proves the presence of antibodies, but also excludes the existence of diphtheria. This fact has been established by numerous observations carried out by me and by American physicians like Park and his assistants. There are but two exceptions to the rule: these occur in virulent or septic cases of diphtheria and in cachectic children. Otherwise, a negative intradermal reaction rules out the presence of diphtheria, even in cases where microscopic examination shows the presence of true diphtheria bacilli. In such instances we deal with angina occurring in carriers of the Klebs-Loeffler bacillus. It may be stated, therefore, that the intradermal test may carry more weight than the result of bacteriological examination.

A positive intradermal reaction only proves the absence of protective bodies—omitting from consideration a pseudoreaction, which need not be further discussed here. However, a positive result does not necessarily signify that the affection present is diphtheria. In this connection it is interesting to note that infection does not always occur, even if antibodies are absent. This applies also to patients who harbor organisms the virulence of which has been established by animal experiments. This phenomenon may be due to mechanical protection derived from the intact mucous membrane against bacterial invasion, just as the skin, as a rule, shuts out infection. This explanation is supported by the observation that infection may occur in chronic carriers who lack antibodies, after operations such as removal of tonsils or adenoids or turbinectomy. Investigations have shown that the presence or absence of protective bodies is a characteristic shared by all members of a family.

Most authorities hold that antibodies are the result of a previous attack of diphtheria. Indeed, it has been shown that they are present in individuals after an attack, who had been unprotected previously. It is important to determine how long antibodies thus formed remain in the organism, or, in other words, how long the immunity acquired persists. It has been shown that antibodies have almost completely disappeared a year after a severe attack; no large scale investigations have yet been carried out after milder infections. It has been suggested that the antibodies, which are found in normal individuals and which have an action identical with those appearing after infection (according to Groer and Kassowitz), are due to an attack of diphtheria within the preceding year. However, there are many objections to such an assumption. Thus a different origin of the antitoxin of so-called normal persons is by no means excluded; conceivably, their appearance might be a function of age.

Another aspect of the problem is the fact that the virulence of diphtheria shows such marked variations in different cases. We may ask, if the predisposition to a severe or a mild attack can be explained.

The early discoveries of bacteriology sought an explanation of these clinical variations by presuming either changes in the virulence of the infecting organism or the presence of a mixed infection. This statement cannot be maintained, since animal ex-

periment has clearly shown that no relation exists between the virulence of a strain or organisms and the severity of infection with this strain. I may add that I think animal experiments offer reliable data for deciding such problems. With regard to the malignant or so-called septic form of diphtheria most authors now agree that it is not a mixed infection, but that all the severe symptoms are due to the diphtheria bacillus. We must, therefore, again refer to the second factor, which plays an important rôle in all infectious processes, namely, individual susceptibility. Morbid symptoms are the expression of the reaction of body cells. It might, therefore, be suggested that variations exist in the susceptibility of cells to diphtheritic toxins, in other words, that severe cases are due to special idiosyncrasy. Though this does not offer a complete solution of the problem, it renders it at least more intelligible.

In my opinion an explanation of the clinical phenomena can be gathered by a consideration of the following observations.

We know that persons may be subject to repeated attacks of diphtheria. According to statements made above this implies that the antitoxins produced in response to the infection and leading to its termination, disappear after convalescence. Therefore, a fresh exposure may result in another attack, and the character of such repeated attacks may show variations; they may be milder or severer than the first. Karasawa and I have reported a case of four attacks of diphtheria, where the intensity of the morbid manifestations increased every time. Examination showed that the patient's serum did not contain any antibodies. Tests were continued throughout the whole period. It was found during the first attack that antitoxin did not appear until the third week after onset; however, in the fourth attack, it was present in abundant quantities after a few days. Though all antibodies formed during the first three attacks had disappeared, yet the infection had left its marks on the body. We may presume that cells had acquired the faculty of producing antitoxin more and more rapidly and abundantly. As Professor Pirquet defines it, the body had become allergic, and, as in the case of other infections, the phenomena accompanying the establishment of immunity took a more accelerated course. Since repeated infection leads to a more rapid and abundant formation of antitoxins, the successive attacks are brought to a speedier conclusion, thus the formation of membrane at the fauces is arrested sooner; in a word, the curative process commences earlier and terminates more quickly. Cases which manifest symptoms of increasing severity in successive attacks may be explained by assuming that the cells had failed to acquire the faculty of accelerated antitoxin formation.

If this explanation is true for multiple attacks occurring in one individual, it may also be held that differences in the severity of first attacks in different patients are based on the same principle. It need only be assumed that the speed and quantity of antitoxin formation is a function of the body cells with a tendency to individual variations. This has been a well established fact for a long time with regard to animals. For it was found that, while

some horses formed antitoxins rapidly and in abundance, others were so unsatisfactory in this respect as to be useless for the purpose. Identical variations can be observed in man, as the immunization experiments carried out by Behring have demonstrated.

It seems justifiable, therefore, to make use of experimental findings in the interpretation of clinical phenomena; thus it may be concluded that the function of antitoxin formation in diphtheria varies in different individuals both with regard to speed and quantity. We may assume that the morbid processes reach their climax and commence to decline as soon as antitoxin appears in the circulation, for from this moment newly formed toxin will be neutralized. It is, therefore, clear that the symptoms of an infection of a given virulence will be the milder the greater the speed and abundance of antitoxin formation. Thus, the most severe manifestations will be encountered in those individuals who are unable to produce it altogether or only after a long delay. In practice children are found to exhibit all grades of reaction between the two extremes. The mildest cases may be expected in patients who did in fact have traces of antitoxin before onset of the illness, though the amount in circulation was too small to be detected clinically

and insufficient to prevent infection. Such children would be specially adapted to react to the stimulus of circulating toxins by producing the necessary quantity of antibodies in the shortest space of time.

Thus we arrive at the conclusion that, in addition to the local protection derived from the intact and impregnable mucous membrane, there are two factors producing immunity against diphtheria: the one is humoral in nature and its presence is determined by demonstrating and measuring specific antibodies in the serum; the other is the cellular factor, which is based on the varying faculty of cells to generate antitoxins.

Humoral immunity signifies absolute protection as long as antibodies are circulating. Cellular immunity, while unable to prevent infection, determines the intensity and duration of the attack. The later and the less efficient the defensive mechanism of cells reacts to the morbid stimulus, the later the effects of the organisms and their toxins can be counteracted, and, naturally, the more opportunity is given for the diphtheria bacillus to develop its dangerous activity. In this way we are able to interpret the malignant forms of diphtheria, which are due to the complete inability of the body to defend itself against the toxins of diphtheria.

Medical Supervision of the Destitute Child*

By MAYNARD LADD, M. D.,
Boston,

Physician in Chief to the Children's Hospital of the Boston Dispensary.

The introduction of social service departments into the more progressive hospitals of the country has greatly increased the efficiency of the medical service rendered to the community. The introduction of medical departments into the social agencies which assume the care of destitute children promises to be equally revolutionary. I have been asked to discuss the way the problem of the destitute child has been handled in Boston, and to present the evidence on which we base our belief that the medical supervision of the boarded out child must be one of the first and most important considerations of any child placing association.

About five years ago Mr. J. Prentice Murphy, who was then secretary of the Boston Children's Aid Society, came to the conclusion that the medical supervision of the children boarded by the society was in many ways inadequate. The policy of placing children in boarding homes, instead of herding them in institutions, had proved a wise measure, but it made more difficult the problems of health supervision. The children were living in homes widely separated. The social visitors were not trained to handle medical problems which were continually arising and the foster mothers were still less competent to do so. Dependence had to be placed upon local physicians in a hundred different

localities. In cases of serious illness requiring hospital care it was difficult to obtain prompt and efficient service. The large group of babies who from necessity were separated from their mothers and fed on substitute foods could not receive the specialized care to which they were entitled. In short, while the social end of the job was scientifically and efficiently managed, the medical supervision of the children from a physician's point of view was very inadequate if not actually bad.

The problem which had to be worked out was how to establish an organization which would assume the medical supervision of the children, correlate the social end of the job, and provide proper hospital facilities for those who became seriously ill. The expense of such an organization was of primary importance. The group of children varying in number from five hundred to eight hundred cared for by the Boston Children's Aid Society and the Church Home Society was not large enough to warrant building up a separate medical department with the heavy overhead expense. The only solution appeared to be to utilize the facilities of a large hospital and so to arrange the work that it would not conflict with its regular service. Thanks to the cooperation and spirit of Mr. Michael M. Davis, then director, the Boston Dispensary was selected for the experiment and the chief of the children's department assumed the medical direc-

*Read before the Philadelphia Pediatric Society and Children's Bureau, May 10, 1921.

torship of the Boston Children's Aid Society and of the Church Home Society. The advantages of this arrangement were obvious. In the first place it centralized the medical care under one responsible head, who by virtue of his connection with the

infrequently happened that their favors have been returned when they have had to face the problem of providing for a convalescent child.

It is only fair to state that there were in the beginning many persons connected with the agencies, and with the dispensary, too, who were skeptical in regard to the success of the experiment. The conservative elements in the societies were fairly content with the services they had been rendering and felt that a preventive clinic would complicate the social problem without any corresponding advantages. Some of the dispensary staff, on the other hand, looked upon the children in the preventive clinic as well children involving no particular medical problem and as likely to prove a source of an-

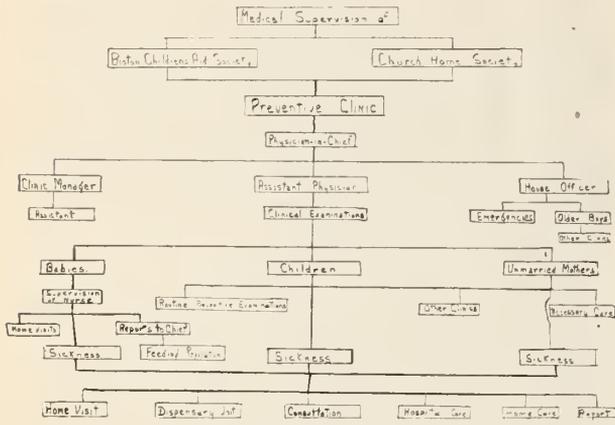

FIG. 1.—General scheme of organization.

dispensary was able to secure the cooperation of the different departments. Small but for the time sufficiently large quarters were set aside for the use of the so-called preventive clinic, with its own corps of workers. The facilities of the clinical laboratory, the x ray laboratory, and the special departments, such as eye, ear, nose, and throat, gynecological and orthopedic, were made available without prohibitive overhead expense. The children's hospital of thirty beds became the natural centre for seriously ill children, thus relieving the foster mothers and social visitors of responsibilities they should not

LABORATORY EXAMINATIONS - SMEARS - WASSERMANS - URINES

Total number of urines	202
Negative Findings (examination in itself)	199
Negative Findings (Positive treatment)	76
Positive Findings (examination in itself)	33
Positive Findings (Positive treatment)	2

FIG. 3.—Data in regard to certain of these clinical tests. A child with a positive vaginal smear would not be accepted by the societies. In two years the occurrence of gonococcal infections has been limited to four cases. We made one hundred consecutive Wassermann tests with only four positive reactions. Since then we have exercised our judgment as to cases which might be placed in a suspicious class. Vaginal smears and Wassermann reactions are made in all cases in which there is physical evidence of vaginal inflammation or discharge; in all unmarried mothers and illegitimate children, in all court cases and children with sex delinquencies, and whenever the history or physical examination leads to a suspicion of venereal disease. About twenty-five per cent. of the children are tested, thus allowing a large margin for error in judgment. Out of 214 blood specimens taken, nine have been positive. Routine Wassermann reactions in groups of children such as these we are speaking of, in our opinion are an unnecessary expense and annoyance. The cases selected for tests could in my opinion be cut down to much less than twenty-five per cent of the whole number, without risk of overlooking an obscure case of congenital syphilis. Undoubtedly this question must be judged differently in different communities, as the incidence of congenital syphilis varies greatly. In a similar examination of the urines in seventy-six consecutive cases (whenever a specimen could be obtained at the first visit) only two gave positive findings. Of 142 selected or suspicious cases, thirty-three gave positive findings. There is much more to be said in favor of routine urine examinations in groups such as ours, but there are physical difficulties in securing fresh specimens when patients are placed miles from the hospital centre and we cannot and do not secure the urine in every case. Whenever a child is reported ill, or in the convalescence from most of the infectious and contagious diseases, great efforts are made to secure specimens for examination.

FIG. 2.—Showing the extent to which the various departments of the dispensary are utilized. The sum total of cases examined and treated in other departments almost equals the visits to the preventive clinic itself. This is convincing proof of the many medical problems which arise when one conscientiously supervises the health of a group of children. In the last fourteen months we have made 202 routine examinations of the eyes of children of school age, with the result that fifty-one children have been fitted with glasses. Note also the fact that in four years we have had only thirteen cases of scabies, a disease which has proved one of the most difficult conditions to handle in some of our cities.

be forced to assume. In the care of contagious diseases, the special hospitals were utilized, but their cooperation was more easily obtained from an organized department of the dispensary than by the individual efforts of the agencies—and it has not

noyance and of very little medical interest. However, the machinery was set in motion and it has now been running for five years. Its usefulness has been fully demonstrated—to the agencies as a means of lowering mortality and morbidity, and to the dispensary as an added service which it has been able to render the community.

The organization of the clinic may be considered in more detail by separating it into groups, all of which are under the one management but with responsibilities sharply defined. The two children's societies have offices located outside of the dispensary building. Their general offices are concerned with social, financial, and administrative details of their work. With them rests the selection of cases,

the study and social diagnoses of families, the preparation of histories of children received, the selection of foster homes into which the children are to be sent, the supervision and training of the foster parents, the selection and training of the nonmedi-

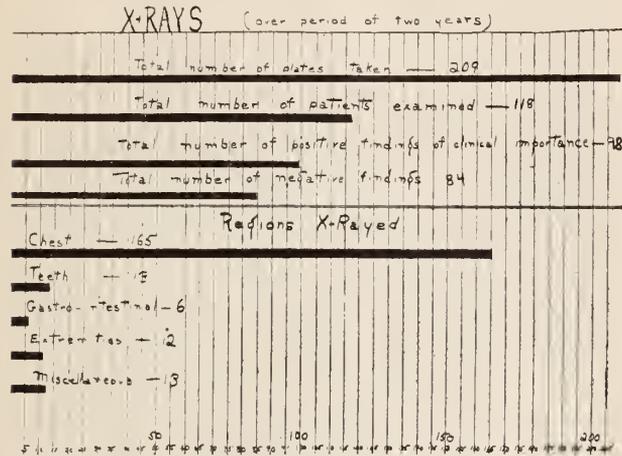

FIG. 4.—Very liberal use of the x ray is made in our first examination. Many of our children have been exposed to tuberculosis, many are undernourished. It is of practical importance to have a record of the chest as shown in the x ray, not only to show lesions which might be overlooked by the ordinary methods of examination, but as a basis of comparison for future examinations. The result of such examination—about half of these plates gave positive findings of clinical importance. If the resources of the societies and clinic permitted I should favor a considerable increase in the number of x ray examinations. As it is now, about one in ten children are x rayed, the thorax being selected in the majority of cases.

cal workers, the social case work supervision of the medical workers, the provision and distribution of special foods, etc., which as a result of their own

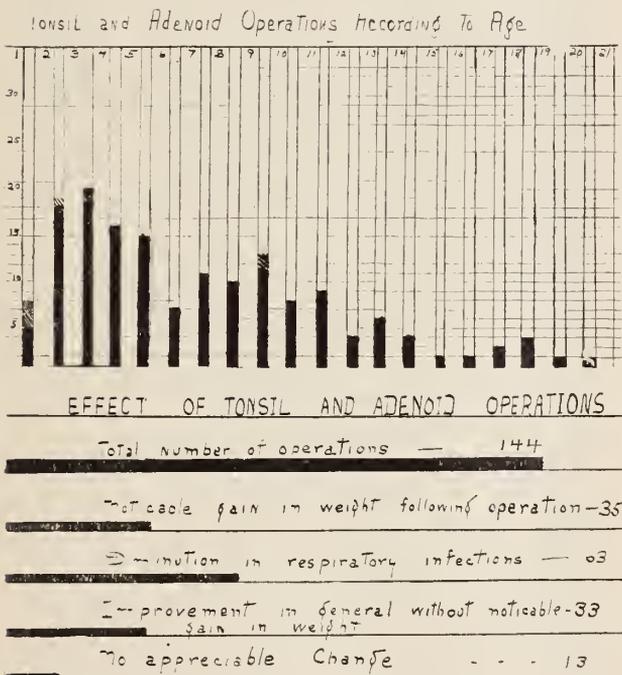

FIG. 5.—Represents a study of 144 tonsil and adenoid operations upon children carefully selected for some definite state of ill health. This group represents about twelve per cent. of the whole number of children accepted by the societies. Thirty-five of this number made a noticeable gain in weight following the operation; sixty-three showed a diminution in respiratory infections, and thirty-three were improved in their general condition without noticeable improvement in weight. In thirteen only was there no appreciable change in condition. The cases are brought to the hospital of the dispensary by appointment in the morning, are examined on their arrival for any evidence of an acute infection contraindicating operation, and remain in the hospital under observation over night, or for longer periods in case of any unfavorable development. There have been no accidents or serious complications in this group.

observation, or that of the medical director, are found to be necessary.

Theoretically, the final disposition of the child, and generally its original acceptance, are decided by the respective societies through their own office group. In special cases, such as with feebleminded children, children still undernourished or convalescing from disease, syphilitic or tuberculous children, the medical director is consulted and the disposition of the child is by mutual consent. Actually, however, the general current of all social case work of these two societies is determined by the advice and counsel of

the medical director. As for example, frequently when from the viewpoint of family conditions the child might well be returned to its own people, the medical director will order a longer period of foster home care because of some special physical or health need which exists in the child.

The preventive clinic at the Boston Dispensary is organized under the control of the medical director of the two societies, whose duties are those of a consultant in all cases involving special decisions or judgments, and who also directs, as his particular charge, the feeding of infants and undernourished children. The routine examinations and home visits are largely made by a full time physician, at present Dr. Leslie H. Macmillan. Her mornings are spent at the dispensary making first examinations and reexaminations; her afternoons in visiting

in their homes children who are reported by the visiting nurses or social workers as ill, but not ill enough to necessitate hospital care.

Both societies follow the plan of having trained graduate registered nurses for the medical social

fitted to influence. The older boys, especially those over puberty, have their first complete examination by the director or by some other physician at the dispensary designated by him.

Notes on all examinations are made in triplicate. One copy goes to the office of the society responsible for the child, one to the dispensary general record files for the benefit of other clinics to which the child may be referred for diagnosis or treatment, and the third is kept on file in the preventive clinic office. The central office is thus informed automatically of everything that transpires in the hospital clinics, and can utilize the knowledge thus obtained in their followup social work and in the final disposition of the child.

A child on entrance is subjected to a thorough physical examination and is referred to special departments when the director or assistant physician thinks it is desirable. When this is done a worker in the clinic personally conducts the child to the chief of the special clinic, calls his attention to the particular points under discussion, and gets a decision promptly and without waiting his turn. If the case is urgent, as for example where carious teeth or diseased tonsils must be removed, the direc-

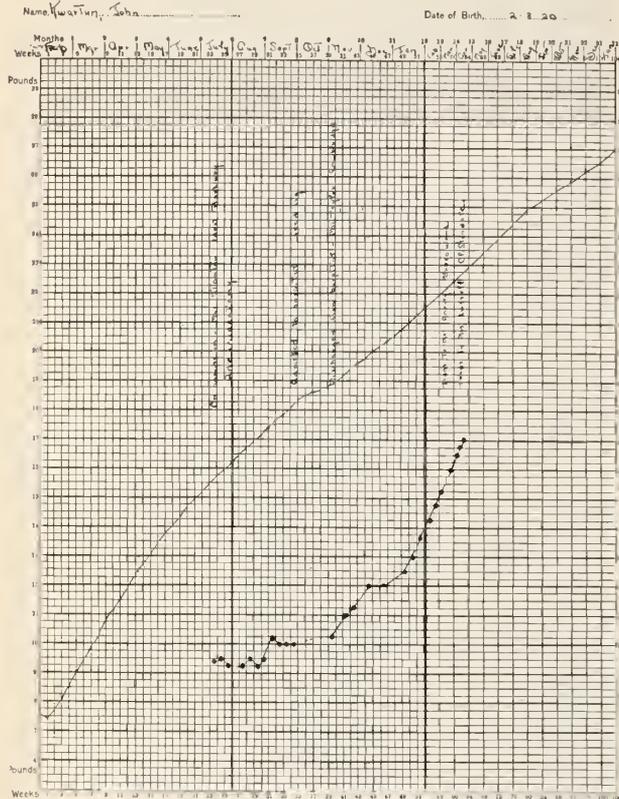

FIG. 7.—J. K., admitted from the Infants' Hospital, and Eye and Ear Infirmary as a difficult feeding case. The solution to the feeding problem was found after four weeks of hospital care, after which the baby made rapid and uninterrupted progress in his weight development.

supervision and training of all their children under the age of three. The assistant physician keeps the director particularly informed of the progress of all problem cases and children who are in any way below par. When conditions press more responsibility upon the foster mother than her experience justifies the child is ordered to some hospital. So far as possible the children are transferred to the Children's Hospital Department of the Boston Dispensary, where they come under the immediate care of the director. Contagious cases are sent to the special hospitals; older children to other institutions, or wherever they can be most effectively treated. Upon their discharge from the hospital they are again brought to the preventive clinic and examined in the light of their recent illness, and their disposition and subsequent treatment is determined by the director.

The importance of an all time physician cannot be overstated; for no consultant of experience could give the necessary time for the daily routine examinations and treatment. With us, a woman physician, on the whole, fits into the place better than a man, for much of her work is with young girls and young unmarried mothers, whom she is better

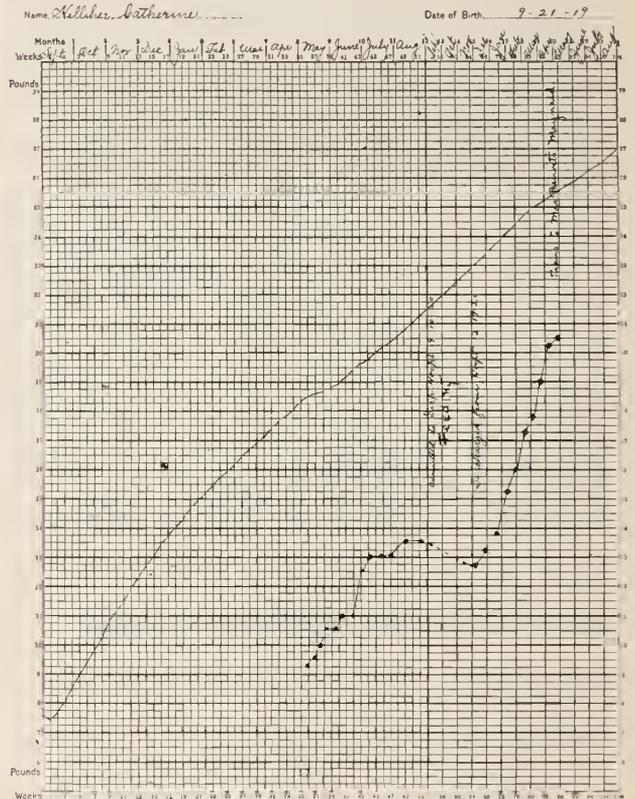

FIG. 8.—C. K., a child from a family with a long and hopeless history. A brother has been in our care for four years. Catherine's development has been considerably more than normal, in spite of a rectal fissure and an attack of bronchopneumonia and furunculosis which required hospital care.

tor recommends that the child be placed by the society in some foster home accessible to the hospital, so that its attendance may be enforced with the minimum of inconvenience to the child and to the central office; for the latter is under obliga-

placed in foster homes at board. This group presents particular problems separate from those of the older children, and to meet them there is a special baby clinic under the immediate supervision of the director. This group requires experience and

curve. Once a week the four nurses meet the director in conference. Each case is carefully reviewed and changes made in food, and the nurse instructed in the principles underlying the changes. They are given directions when next to report.

The foster mothers are always in telephone communication with the nurses. Any unfavorable symptom is reported. The nurse visits the child, gives directions herself to the foster mother if the condition is not serious; otherwise reports the case to the assistant physician, who visits the child. If in her judgment it is necessary, she reports to the director and he either prescribes the treatment or orders the child to be brought to the clinic for his own examination, or arranges for its admission to the hospital. The results of this close supervision are seen in the low mortality rate, and in the almost normal development of the babies, even though bottle-fed. The educational value of such a system of supervision upon the foster mother, the social worker, nurse and doctor, is very valuable and points the way by which large groups of destitute babies may be successfully reared without institutional care with minimum expense and with a comparatively simple organization.

The results of four years' operation of the present method of supervision are shown in Fig. 6. The total number of individual patients carried in the four year period from 1916-1920 was 1,127, representing about 530 cases carried each year. The total number of deaths in four years was twenty-four, or an average of six deaths per year. This represents a mortality of 2.12 per cent. for a yearly average of 282 new patients, or 1.13 per cent. for an average of 530 patients carried each year.

The mortality rate by age is seen in Fig. 7. The figures represent individual cases carried during the four year period, and include all deaths of babies registered as wards of the Boston Children's Aid Society and of the Church Home Society, whether they occurred in the homes or in hospitals. The mortality rate of three per cent. for the first year babies, and 5.7 per cent. for the second year babies represents the total mortality for the four year period. The causes of death bring out the interesting fact that during the four year period there have been only three deaths from gastroenteric disorders and malnutrition, two of which were hopeless when taken by us from an institution—one dying in twenty-four hours and one in seven days. When one considers that there were 459 individual babies in the first two years of life in this period one realizes that the elimination of deaths from gastroenteric disturbances depends upon conditions within our control. These babies were fed upon substitute feeding from the time they came under our care. Not only has the infant mortality in this group been reduced to a point far below what has been considered the minimum for the community but the nutritional development of the child from birth to two years has been considerably above the normal development for their ages as shown in Fig. 8. These latter figures are for the three year period 1916-1919 and exclude cases carried for less than one month.

THEODORE W. L. BRYCE, CLINICAL M. D.
CHIEF, PEDIATRIC DEPARTMENT, IN CLINICAL
AND HOSPITAL LABORATORIES

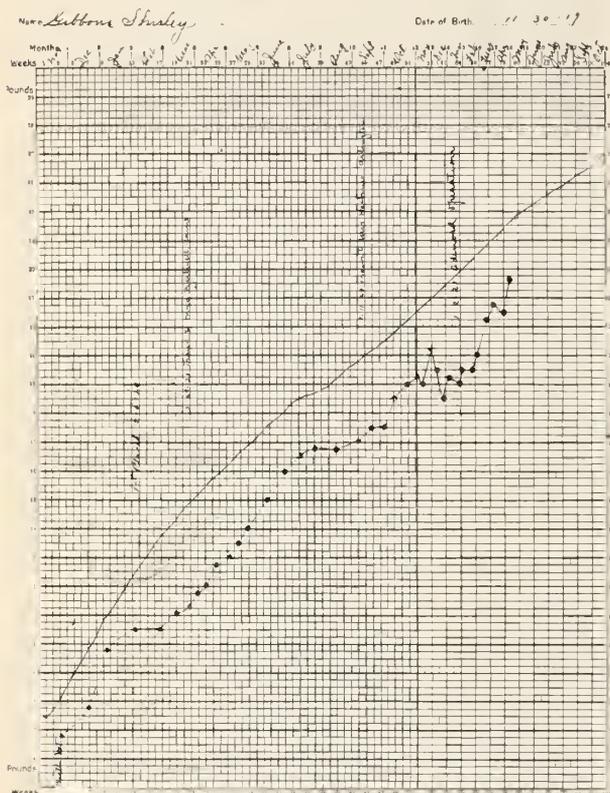

FIG. 11.—S. G. This patient was interesting on account of being an illegitimate child of a tuberculous mother and was nursed three months before we took her. She made one hundred per cent. weight development and so far has escaped tuberculous infection.

judgment in the matter of substitute feeding, for very few of these babies have mothers to nurse them. It is in such a group that the greatest danger lies, and in which the child placing agency without medical guidance is bound to go far astray. However experienced a nurse may be, she needs the direction and supervision of an experienced pediatricist. The difficulties of handling such a group are great. The physical exertion and expense involved in transferring so many babies to a feeding clinic from widely separated foster homes would be very costly. We have organized the preventive clinic for these cases with the idea of getting the maximum supervision with the minimum expense and trouble.

The babies are divided into four groups, each visited by an experienced trained nurse. All babies are examined in the clinic at the time they are accepted by either of the societies. The details of feeding are then carefully formulated and the child is placed in its foster home. The nurse visits each home once a week, or once in two weeks, examines and weighs the baby, goes into details of the hygiene and preparation of the feeding with the foster mother, and makes upon special record blanks notes of the case, and on a weight chart plots the weight

The Nervous Child*

By CHARLES W. BURR, M. D.,
Philadelphia,

Professor of Mental Diseases, University of Pennsylvania.

Dr. Leonard G. Guthrie, in his charmingly written and thought provoking book, *Functional Nervous Disorders in Childhood*, from which I have culled much wisdom and science, divides neurotic children into two great classes: in one, the unrestrained emotional type, the child makes no attempt to control or hide his emotions, in the other, the restrained emotional type, pride compels him to pretend stoicism. In the first class, intellectual power may be, indeed usually is, above the average, but emotionally the child is a bundle of contradictions. The young victim of a despotic nervous organization is imaginative, often superstitious, high spirited but timid, worried by trifles, vain, feels he is unappreciated, craves sympathy, has no idea what discipline means, learns quickly but instantly forgets, works feverishly for a short time and then idles for days, suffers remorse but repeats the offense, is affectionate but his love is purely selfish. As Guthrie says, many of these children eventually become the mainstay of rest houses; a few attain great success in art or literature. Physically they are thin and slimly built. They suffer from night terrors and migraine, and sometimes, but by no means always, are sickly and physically weak, and have poor vasomotor balance, as shown by profuse sweating and cold, damp hands and feet. They, especially the sickly ones, feed the army of the hysterics and neurasthenics in mature life. Insanity often closes the long melodrama.

Children of the second type have strong emotions but try to hide all signs of feeling. They are observant and intelligent, but so reticent they are often thought to be dull, sullen, and obstinate. They are sensitive, shy, and proud. They yearn for affection but are too shy to show it and brood over imaginary slights. They misinterpret the conduct of others and, being suspicious, are unresponsive to friendly overtures. They are solitary, introspective, and have occasional outbursts of furious anger. They have phobias, pass through periods of religious experience and possess no sense of humor. They are prone, at the best, to become incurable sexual neurasthenics, hypochondriacs, mischief making spinsters, or crossgrained and useless old bachelors; at the worst, they become delusional lunatics and may murder supposed persecutors. Few of them attain distinction in any worth while work, though they may in manhood be industrious in a commonplace way.

Many children, of both types, show at some time some physical signs of nervous disease. They are prone to be peevish infants, to have outbursts of infantile anger without physical cause, and at seven to ten years tics (so-called habit spasms) often develop. They are sometimes spasmophiliacs, i. e., the local reaction to percussion of muscles is greatly

above the normal and they are prone to diseases characterized by spasms. Cyclical vomiting is frequent and asthma very common. As soon as they are old enough to be put on a mixed diet, finding food suited to them is a serious problem. Parents think them whimsical and capricious in their likes and dislikes, but the matter is more complex and has deep seated causes. They crave certain articles because of peculiarities in their bodily chemistry, and since all sensory stimuli, those arising from articles of diet quite as much as others, cause in them an associated emotional tone much stronger than in the average child, the color, smell consistency, and general appearance of anything offered them to eat causes much more pleasure or disgust than in the healthy youngster, who cares only for taste and smell. Their esthetic sense and cellular chemistry together cause their gustatory likes and dislikes. They are often stammerers. They are not very subject to St. Vitus's dance, and I am not in agreement with the prevailing medical opinion that the occurrence of this disease is a sign of inherent nervousness in the person affected. It is true that all children during an attack are fretful, peevish, easily frightened, and that sometimes serious mental symptoms appear and become so severe as to end in acute insanity, but the great majority of sufferers from St. Vitus's dance are inherently normal and suffer a mere temporary nervous upset during the acute illness. On recovery from the disease they again become nervously normal. But St. Vitus's dance must never be confounded with tic, which is a sign of a defective nervous heredity and is a somewhat serious warning of future neurotic trouble. My opinion is based upon the fact that very few of the several thousand children who have been treated, many of them for several attacks, at the Orthopedic Hospital and Infirmary for Nervous Diseases, have returned later for any functional nervous or mental trouble, whereas frequently patients, who in mature life come because of hysteria or some other mental disorder, have been treated there in childhood for tic. My experience in private practice has been similar.

Children of both types are victims of an abnormality of personality: their disease is one of personality. They present three problems for study. On what does personality depend? What are the causes of abnormality of personality? What can be done to make the abnormal personality normal? Personality is the thing which differentiates every human being psychologically from all others, which gives him his psychological individuality. It is the sum of his intellectual ability, his moral sense, and his emotions.

He would be a brave man who tried to answer the question, What makes personality? The theological view, that it is something independent of physical organization and is tied up with the soul,

*Read before the Philadelphia Pediatric Society, April 12, 1921.

may be correct, but men of science, as such, cannot study the soul and, as men of science, have no right to an opinion on such a matter because it is outside the domain of knowledge and belongs in the realm of belief. From the point of view of the man of science, personality depends upon the individual peculiarities of the anatomical makeup and physiological working of the human machine. Personality, from the viewpoint of science, is a result of the working and interworking of all the organs and systems of the body. Some systems are more important than others. Of course, the brain is the great organ of thought and feeling, but it can be so hurt by failure of other organs as to be thrown out of gear and made to function abnormally, though every disorder of mental function does not alter personality. For example, if the personality has previously been healthy and has become fixed and crystallized, injury and disease, even of the brain itself, though they cause intellectual defect or disorder, may not change the personality. Purely nutritional disorders, even if they occur during the period in which personality develops, i. e., during infancy and childhood, have little or no deleterious influence. Thus rickets does not, in the slightest degree, cause an abnormality of personality. Indeed rhachitic dwarfs are often blessed with a shrewd, cunning wit. The acute infections of infancy and childhood do not cause the nervous child. When they affect the brain permanently, they cause idiocy or imbecility or that sad condition, aphasia with hemiplegia, usually resulting in mental defect largely from the speech disorder. Acute infantile mania, which I believe to be more frequent than is commonly supposed, also leads to a complete mental breakdown; not an alteration of personality, but its destruction, very early in life. The causes of the condition we are studying lie deeper, and do not result in visible and gross destruction of brain tissue with a corresponding abolition of function, but in perversion of function without a discoverable lesion.

The fundamental factor in the formation of personality is heredity. The immortal stream of protoplasm, which has never ceased to flow since life began, carries with it from generation to generation qualities or rather potentialities, varying in number and complexity with genera, species, and individual families within the species. What happens to any one stream in the human branch of the river of life (any one family) whereby new potentialities arise, whether for evil or for good, we do not know. We do know that characteristics acquired by the individual from without are not carried over, whether they are physical or mental. Thus a man with little natural aptitude for mathematics, who by long training has acquired a great deal of mathematical knowledge, will pass on to his children only the mathematical ability with which he was born. You cannot breed a race of mathematicians by teaching that science to successive generations of ordinary mortals. If a college professor of merely commonplace ability, who has passed his life in the study of pedagogic problems, breeds children and grandchildren who also become college professors, they do not increase in professorial ability as the

generations pass, even if in each generation the organ of thought has been, by practice, trained to its highest professorial efficiency. This is rather fortunate, for the consequences to the world of breeding a race of superprofessors would be rather dreadful to contemplate. The king born with the sneak thief's personality but never becoming a sneak thief, because kings do not need to indulge in petty crime, will probably have a son like himself, unless inheritance is wholly from the mother, no matter what care may have been exercised in choosing the child's environment and in guiding his education.

On the other hand, we know that in an apparently commonplace and ordinary family, there may appear at any time a child whose personality differs, it may be for evil or for good, entirely from its forebears. I am not of course speaking of cases in which parental disease (syphilis) infects the offspring and causes blight, or where accident or injury injures the brain and causes physical disease and hence mental defect, but of cases in which seemingly healthy, but ordinary, parents conceive a child who is a genius or a born criminal, or one of these nervous children we are discussing. There must surely be a physical cause and it may be that, while in each parent each system (brain, bloodvessels, endocrine glands and the rest) is adapted to the others, in the offspring the combination of systems, their interrelation, is bad. I can conceive that a vascular system *a*, in one parent, may be just suited in structure to work well with his adrenal system *b*, while if it is hitched on, by inheritance, to an adrenal system *c*, in itself entirely normal, inherited from the other parent, the result may be bad.

Knowledge, at the moment, seems to indicate that certain of the endocrine glands have much influence on personality and it is becoming fashionable to talk of hyperthyroid and hypothyroid people. Whether fashionable scientific opinion will turn out correct only time will show. Certainly disease of the thyroid may cause mental and emotional symptoms. For example, a boy was bright till his twelfth year. He was easily head of his class, he was fond of play, happy, cheerful and with fair imagination. Then he rapidly became lazy, fell to the foot of the class, ceased to have any imagination, rapidly put on fat and became dull, inert, and, looked at superficially, appeared to be an imbecile. He could not be driven to play, nor roused to any joy of living. When put on thyroid he recovered in six months. He was a hypothyroid. I am inclined to think that some of the nervous children are hyperthyroids. Hypothyroidism deadens rather than perverts personality. It may, however, as one often sees in cretins, increase the feeling of the joy of living, but so far as intellect is concerned it destroys ability; it does not cause perversion of function.

The nervous child, of the first type, may become a poet, even a great one, a musician, even having creative art, and, more rarely, a painter or sculptor. (I suspect that when we learn of the childhood of the sincere and intelligent followers of the newest schools of painting we will find that the percentage of nervous children among them is very large.) He may, in short, become a great artist, but he never can become a great administrator, a great man of

affairs, statesman, general, or leader among business men. He will not become a philosophical man of science, but he may be a religious leader, especially in the ranks of heresy, schism, or false doctrine. When made on a smaller scale he may grow into a sincere Bolshevik, amateur or professional, or an uplifting sociologist. I am quite sure, that many of the men and women who are attempting to save the world today, by trying to destroy it, are examples of untreated, or unwisely or unsuccessfully treated nervousness in childhood. They have all the earmarks.

Let me draw a few illustrations of the nervous child from biographical literature. I can give only fragmentary bits from the lives of distinguished men, because biographers are rarely psychologists, have no interest in the study of behavior as influenced by psychological trends, and regard mere trifles of our external life as vastly more important than things showing the nature of the boy. As a student of human nature, I would rather know whether a small boy was social or asocial, cruel to animals and little children or fond of them, feared the dark or braved all its dangers, lied because of fear of slight punishment, or only when the punishment was sure to be severe, shared the schoolboy's sense of honor or was a hypocritical little prig, walked with shoulders straight or with a slouch, played outdoor games well and with zest or badly and on compulsion, and was graceful or awkward in movement, than to be told the stuff most biographies contain. Still we can learn something from the books. Thus I have discovered only a little about Jonathan Edwards but that little is significant. At ten years he wrote a semihumorous tract on the immateriality of the soul, entered Yale at thirteen and at fourteen was profoundly influenced by Locke's *Essay on Human Understanding*. At seventeen he had a religious experience that satisfied him of his conversion and made him see that the doctrine of the election of some to damnation and of others to salvation was not "a horrible doctrine," but "exceedingly pleasant, bright and sweet." Such certainty about the purpose of God, the universe, and his own infallibility is pathological in a boy no matter what it may indicate in a man.

Lord Byron's mother was passionate and given to shrieking. He was an only child, of violent temper or rather sullenly passionate, but also affectionate. Classmates say of him he was lively, warm-hearted, high spirited, passionate, resentful, venturesome and fearless. Mentally he developed very quickly. He read the *Old Testament* through with pleasure before he was eight years old, but when he came to the *New Testament*, found it a task. People not encumbered with religiosity and remembering their own childhood, will comprehend his reason and sympathize with his attitude. He fell in love at eight and at sixteen, on hearing of the girl's marriage, almost fell into convulsions. He wrote *Hours of Idleness* between his fourteenth and eighteenth years.

John Forster says of Dickens, he was "a sensitive, thoughtful, feeblebodied little boy, with an unusual sort of knowledge and fancy, and with a dangerous kind of wandering intelligence that a

teacher might turn to good or evil, happiness or misery, as he directed it." As a child he was subject to spasms, was never a good little cricket player, nor was he first class at marbles, or peg top.

Friedreich Nietzsche's father was insane. The son was always supersensitive and began to examine his conscience at nine years. He improvised on the piano and studied ballistics at ten years. At fourteen he wrote the history of his childhood and mapped out a vast program of study of geology, botany and astronomy.

Percy B. Shelley, as a child, was very sensitive to pain and subject to paroxysms of passion. Once he even seized a smaller boy and flung him at his persecutor. He was a strange unsocial being and did not care for outdoor play. Once only he walked in his sleep, but day dreamed often throughout childhood and youth. He early became an omnivorous reader.

George Meredith asserted that he had an unhappy childhood but really his parents spoiled him. He feared ghosts and the dark. He did not care to play with other children, was very introspective and "assumed an air of superiority." He never played outdoor games and his companions thought him "a cocky prig." At fifteen years he had a spasm of religion, lasting about six weeks and making him a nuisance to everybody, as he repeatedly asked them if they were sure they were saved. He is the classical example of the boyhood of the prig. One weakness he carried through life; he did not care enough for the memory of his mother to refute the silly stories about his being the natural child of great people.

Did time permit I could multiply indefinitely, from biographical literature, cases of nervous children who became men and women distinguished as novelists, poets, dramatists, painters, and both creative and performing musicians. I could quote from my private records histories of more than a few of the same kind of children who never reached distinction, because in them intellect was not so highly developed that they could do work attracting the attention of the world. My records also agree with biographical literature in proving that the offspring of these people are more prone to be degenerate than are the children of average people. In all, the childhood history is the same; there is a very early and rapid development of mind and the emotions, a total lack of emotional control shown by causeless fits of anger and not infrequently spasms, not epileptic but emotional, sleep walking and sleep talking, delirium with the slightest fever, intense supersensitiveness and extreme selfishness, a lack of the sense of duty towards others, and precocity in the growth of the love feeling long before sexual desire has been established, being indeed asexual. The time of crisis is at puberty. If they pass that successfully, or rather if they fight successfully through the period of adolescence, they may become in spite of their handicap, even brilliantly useful men and women. Otherwise they become useless and, embittered themselves, they make the world bitter to others and if they breed, breed weaklings.

I do not wish you to get the impression from anything that I have said about the nervous child, that

I believe there is a class of children, clearly marked off from all others, children we can put in one pigeonhole, and that I or anyone else can draw a line and say on the one side are gathered all the normal, and, on the other, a special class of the abnormal, the nervous. Such a belief is absolutely incorrect. There are not only no clearcut boundaries between the different types of the diseased but no clearcut line between the healthy and the diseased, the normal and the abnormal. All types of men merge into each other. There are all degrees of health and of disease and pathological qualities are found in queer companionship with health. Every child is, then, a mixture of healthy and unhealthy potentialities and this increases the interest in and the importance of the study of the nervous child, because in planning treatment much will depend upon whether the healthy or the unhealthy potentialities are the stronger. The personality may, because of inherited tendencies, be so warped and twisted that we can do nothing, or the inherent tendency towards health may be strong enough to win out, if the child is wisely managed. The wise physician will guess the riddle rightly: the unwise will rush in with optimism to cure the incurable, or fail properly to handle the curable. One frequent error is to mistake the unbalance many boys have at puberty for degeneracy. It is not. A wise schoolmaster or physician will not be frightened because a boy suddenly says or does something out of consonance with his previous conduct, whether he is a nervous boy or a much to be envied healthy young savage, because he knows that every boy passes through several stages before he comes out a human being. The superficial psychologist of the Freudian school will frighten the parents and, if the boy is left with him long enough, probably injure him unless he is made of very good stuff.

The treatment of the nervous child is important because he is so often the starting point of degeneracy in a family, and, on the other hand, because much of the world's higher work in things above the material, things higher than inventing motor engines and telephones and cotton gins, things more important than those which increase opportunity for soft luxurious living, has been done by people who certainly were nervous children. Too often, because of parental ignorance, they have been neglected and all through childhood have fought their own battles toward health, not only unaided by good environment but held back by bad, whereas they should have been helped in all ways to do the work they were fitted for. The nervous child has so often fought his own battle successfully that one is inclined almost to believe that our efforts in influencing Nature are wholly futile and that what will be, as determined by inheritance, will be, no matter how hard we may try to change the current of development. Would Dickens have done more or better work in manhood had his childhood been passed under theoretically better conditions? I doubt it. Would an environment such as is advised by what calls itself the newest school of pedagogy and sociology (the school of psychoanalysis) have increased his capacity for creative work and his happiness? No.

We can do something, sometimes a great deal, to help the nervous child to find permanent healthy balance. The matter is not one of giving physic. In the dim distant future, when we really know something of biological chemistry, when our chaotic knowledge of those glands now attracting so much attention, becomes much greater and we really know what their functions are, and how performed, we may be able to stabilize the emotional side of children by medication, by giving this or that chemical substance. Today we must use other means.

Nervousness depends upon, in fact it is, emotional instability, lack of inhibition, absence of will, enslavement to impulse. The one object of treatment is to strengthen the will and dethrone the tyrant impulse. This is a hard task at best in a healthy world; today, in a sick world, itself suffering from the very disease we want to cure, the task is harder.

Before entering into the question of treatment, I wish strongly to protest against certain teachings, advanced by people who assert that they have discovered what they call a new psychology, which is largely advertised in newspapers and the popular magazines under the name of psychoanalysis. The literature on the subject is enormous and is growing daily. Starting out as a method of treating hysteria, it now lays claim to being a great system of philosophy, explaining all things. It has expanded into an educational system. The disciples of psychoanalysis say there is a subconscious mind which is the real personality. It reveals itself in dreams. According to them, consciousness exists in utero, and libido begins while the fetus is swimming in the amniotic sac and repressed, unconscious sexual desire causes practically all emotional disease; conscious sexual desire they pay little attention to. A boy's dreams reveal sexual desire, which may have been unconscious since he was an unborn fetus; though unconscious or subconscious it controls him. Treatment consists in having the patient describe his dreams to the psychoanalyst who interprets their symbolism. The symbolism is to say the least peculiar. Any elongated object, an umbrella, a toadstool, a key, water, animals, and a thousand other things are symbolic of the sexual organ or act. The patient is cured by having his unconscious desires explained to him by the interpretation of his dream. This doctrine is being preached by men and women who lay claim to being decent, and who say that we, who know it is indecent, are ourselves dirty minded.

Several writers are clamoring for the introduction of psychoanalysis in the normal schools, social teachers may practise it on their young pupils. Need I tell you what the effect on nervous children such examinations would have? Sexual feeling has much to do with hysterical disorders, but it is not unconscious or subconscious and does not date back to thumb sucking. Another fad is the cure of disorders of personality by surgical operations on the skull for supposititious fractures in infancy, and a third is the cure of badness by removal of adenoids.

Now as to real treatment. It is a matter of education, which is a very different thing from mere school training. First, parents must change their attitude toward life, must get away from the pre-

valent belief that it must be made easy, that luxury is the thing, and must relearn the lesson that inhibition is the one thing children must learn. We must cast aside the false doctrine, that to save a boy you must remove all temptation, prevent all stress, and give him no battle to fight. He must be made strong to fight the battle against evil. We must relearn that innocence, which after all is ignorance, though pretty in a baby is hideous in an adult; that hiding nasty truths does not make them untrue or abolish them, and that work is the one thing worth while. Our public educational system increases the numbers of nervous children because it teaches not truth but falsehood. It teaches that life should be easy, that society must care for everyone. In some schools ranking has been abolished on the ground that it hurts the feeling of the boy who cannot be at the head of the class (really a sensible boy cares naught for such things) and that competition is an evil. More than one pedagogue teaches that children must not be allowed to play with soldiers lest a spirit of militarism develops; others, that history is useless, because, forsooth, what can we learn from Greece and Rome, and the founders of the Republic can teach us nothing because the world, i. e., man, has so changed. Fairy tales, these unwise educators say, must not be told to children lest they aid in the development of imagination, but wise men know imagination is the world's great need. Women, we are told, are the best teachers because they are so gentle, but we know that no boy over ten years old should be taught by women.

Our system of trying to make education universal is fundamentally wrong because it is wasteful to prodigality: many boys and girls are incompetent to take in anything beyond the merest fundamentals, and both public money and their time is wasted by trying to make bookish people of them. Money that should be spent on intellectual boys is wasted

on children whom Nature intended should work only with their hands. To hold them in school does them no good and much harm. They want to work, the years of idleness at school destroy that desire and they become lazy. The one thing to make a boy a man is to teach him selfcontrol, a love of truth, and a desire to work. These are the important, vital things. Our public school system, far from helping the nervous boy, is injuring him, and many boys, just on the borderline, it pushes over.

The parent's part in the training of children and in the prevention of nervousness is of more importance than that of the school. Today parents are in a very unpleasant situation. If they are wise, they may overcome to a greater or less degree the evils of our effeminized public school system, with its superficiality, lack of discipline, multiplicity of useless studies, absence of real and prompt punishment for boyish sins, mixing of sexes and of races; if the father, and especially the mother, are unwise, only Nature can help the child. Fortunately Nature often does help by giving the boy a strong enough healthy tendency to health to overcome the evil potentiality.

I have said little or nothing as to medical and surgical treatment. It can be summed up in a phrase, the nervous child's anatomical apparatus should be kept in good condition and if he has any defect therein, it should be remedied. If he really needs glasses he should be fitted with glasses; circumcision is a wholesome practice in all boys and, if the prepuce is very long or adherent, it is imperative; adenoids should be removed always, tonsils sometimes, teeth should be looked after, but boys should not be tortured for years for the sake of prettiness; noses that fail as organs of respiration should be seen to, but we must not expect miracles by the removal of so-called reflex causes of disease.

Psychoses and Potential Psychoses of Childhood*

By EDWARD A. STRECKER, M. D.,
Philadelphia,

Senior Assistant Physician, Pennsylvania Hospital, Department for Mental and Nervous Diseases, and Chief of Clinic for Mental and Nervous Diseases.

True mental disease in children is extremely rare. Hagen (1) stated that it occurred in but one of every 17,752 inhabitants and in more recent times Rhein (2) in addition to five cases in his personal experience was able to collect only forty-four instances from the literature. Melancholia in children was first described by Berkham (3) in 1750 and what is undoubtedly a description of the youngest mental patient on record was a case of insane fury in a nine months old infant, published by Greding (4) in 1790. We should be skeptical about this report. Probably if a pediatricist had been present a more reasonable diagnosis of intestinal colic would have been made.

STATISTICS.

A review of five thousand consecutive hospital admissions brought to light only eighteen instances of undoubted psychoses in children under the age of fifteen. This is less than one half of one per cent. of the admission rate. Ten of the children were girls and eight were boys. The type of mental disease was doubtful in four cases. In ten the final diagnosis was manic depressive psychosis. In seven of these the depressive element was more pronounced and in only one was there frank mania. These statistics do not include postinfectious mental disease, juvenile paresis or psychotic manifestations, or episodes in epileptics, psychoneurotics, constitutional psychopaths, or the mentally defective. However, dementia præcox was carefully searched for

*Read at a meeting of the Philadelphia Pediatric Society at the College of Physicians and Surgeons, April 12, 1921.

and only four examples found. It is likely that this extreme rarity is more than accidental. When one recalls that this disease has its greatest incidence at puberty, or soon thereafter, and that a wealth of endocrine anomalies and disorders have been noted in the fully developed and chronic stages of the psychosis, it would seem that we have a clue too significant to be overlooked in future attempts to uncover hidden etiology.

The age of incidence in the manic depressive group was as follows: one at ten, three at twelve, one at thirteen, and five at fourteen. In dementia præcox the age at onset was eleven and fourteen in the male children and eleven and thirteen in the females.

CASE REPORT.

I have selected one case of dementia præcox for brief description. The patient's heredity was heavily charged. The father had melancholia and a paternal uncle and cousin were mentally sick during the greater part of their lives. The child was bright, in fact, precocious. Coincident with the establishment of the menses at thirteen, she became irritable, seclusive, depressed, and made two dramatically planned attempts to end her life. A brief remission was followed by rapidly progressing and final deep dementia. There were hallucinations of hearing, silliness, vague ideas of reference, delusions of persecution, untidiness, and frequent outbreaks of catatonic excitement, during which she blindly and desperately attempted to injure everyone in her vicinity. At the present time, in the fourteenth year of the disease, at the age of twenty-seven, she is hopelessly demented.

SYMPTOMATOLOGY.

It seems probable that the symptomatology of mental disease is relatively more simple in children than in adults. In the manic depressive group, the depression was often nothing more than an elementary emotional reaction or else it was supported by vague and trivial delusional formation. In only one patient was the idea of personal wrongdoing and selfdepreciation expressed comprehensively and more or less logically. The psychomotor activity was seemingly more motor than psychic and the distractibility and flight of ideas were apparently very closely related to the contents of the environment. Mental confusion occurred frequently. In dementia præcox delusions were usually of uncomplicated construction.

It must be borne in mind that the central nervous system, particularly in respect to its more complex differentiation, is the final acquisition of the child. A structure or organ which has not reached its maximum growth is unable to respond by complete functional expression to either physiological stimulation or pathological irritation. Among primitive races mental disease, especially dementia præcox, is uniformly simple in its clinical expression. For instance, among the Javanese, Kraepelin (5) found a preliminary period of confused excitement which rapidly passed into a silly dementia. Catatonia was infrequent; hallucinations rare; delusional formation very elementary and prodromal depression absent.

MENTAL SYMPTOMS IN DISEASES OF CHILDHOOD.

Of particular importance to pediatricists are the mental symptoms which occur in the course of, or as sequels to the infectious and contagious diseases of childhood. They are very frequent. Alexander (6) states that between ten per cent. and thirty per cent. of psychoses in children are due to acute diseases, especially the exanthemata. Spitzka (7) found that seven per cent. followed fevers; mental episodes have been reported after scarlet fever, diphtheria, whooping cough, typhoid, and malaria. During the course of the acute illness we may expect a varying grade of delirium and subsequently an unmotivated excitement or depression with considerable confusion, often without hallucinations and delusions. Of recent interest are the psychoses which follow epidemic encephalitis in children (8). The clinical picture is more or less uniform. There are impulsive, purposeless motor acts, marked irritability, attention disorders, distractibility, an inconsistent, variable, and unstable emotional reaction, marked insomnia, and occasionally intense eroticism and precocious sexual feelings.

It seems likely that the frequency of mental disorders in the common diseases of children is another expression of the structural and functional incompleteness of the central nervous system. In other words, the resistance which later will be highly developed, is still in an unstable and formative stage.

POTENTIAL PSYCHOSES.

To judge from the case histories of adults with mental disease, there is often in childhood a predisposition which is expressed in terms of abnormal makeup. How may these potential psychoses be recognized? In children who are brought to the clinic we not uncommonly meet the shut-in type of personality. These children, as Dr. Burr once aptly wrote, are a curious combination of child and adult. Intellectually they are often precocious. Socially they are not boisterous, vivacious, or openly inquisitive, but show a passive resistance to their environment. They do not enjoy play with other children, are much alone, and do not readily confide their thoughts to others, even to their parents. They are unduly sensitive and often absentminded and dreamy. On such a basis may develop distinct seclusiveness and a gradual withdrawal from practically all human contacts. This is essentially dementia præcox, the preeminent psychosis of adolescence.

While a manic depressive temperament often exists in the adult, it is less clearly recognized in early life. A certain percentage of children show an undue amount of emotional instability often with pronounced moodiness and sulkiness. I have under observation several intellectually supernormal boys who present almost constant and uncontrollable motor restlessness, which if accompanied by corresponding mental hyperactivity would be equivalent to true mania.

MENTAL HYGIENE.

The pediatricist has the unusual opportunity of studying and sometimes controlling the environmental factors of childhood. While to some extent

the child is limited by its heredity, it is undoubtedly true that much of the future is determined by early influences and training. Without attempting to discuss preadolescent psychology, it might be worth while to point out certain elementary facts. It is probably true that in the early years of life there is an effort on the part of the child to dominate its immediate surroundings. When the path of least resistance is followed by the parents the outcome is a spoiled child. When the opposite extreme method is used, and there is constant severity and harshness, we may expect a repressed child with a crushed spirit, either vindictive or lacking in initiative and courage. What is needed is a reasonable, middle of the road course.

Most normal children are animated interrogation marks. Their curiosity, and especially their sexual curiosity, needs to be taken seriously and generally frankly. If denied by the parents or physicians, the desired information will soon be supplied by questionable sources which may prove highly dangerous.

Punishment of children is a much mooted question. It is generally conceded that it is harmful to the child, if it occasions a marked loss of reasonable emotional control in the parent or individual who administers the punishment. Usually it is possible

to build up more logical barriers against bad behaviour. Children are individuals and have their own point of view and the adult conception may be totally inexplicable and seemingly inadequate to the youthful mind.

Finally no two children are alike. There are personal differences and peculiarities which must be carefully studied. Certain traits need to be encouraged and others discouraged, if the child is to reach the apex of its inherited and developmental possibilities.

The Problems of Personality in Disease*

By MARION E. KENWORTHY, M. D.,
New York.

In order to have an understanding of the mental aspects in any given case, we must first have a clear conception of the personality makeup of the patient, and so it is pertinent to ask, What do we mean by personality? It is not my intention to give a long didactic definition of the concept of personality, for it would be confusing. Paton, in his discussion of personality, states it well when he says: "The personality expresses the individual's biological capacity for adaptation, and in a certain sense measures the degree of adaptation of which he is capable at all the different levels of living, reflex, autonomic, and voluntary."

In our consideration of personality this concept must be borne in mind, that the kind of integration with which we are dealing is not inherited, but is acquired in the course of the life time of the individual; hence it is possible, arbitrarily, to divide the growth of the personality into various stages, and for the sake of convenience we may designate the first stage as the intrauterine, the second as the infantile, the third as the preadolescent, the fourth as the adolescent, and so on through the life span of any given individual.

Thus it will be seen that as the individual progresses through each period of his development, his experiences involve a more and more complex organization of the nervous system. Concurrent with this growth, we find larger and larger association

areas becoming involved. Therefore, in the consideration of the personality of any individual, we must bear in mind the necessity of obtaining a concept which contains a longitudinal section of the individual's life rather than accepting as sufficient data that which we can obtain by taking a cursory cross section observation. That is to say, it is always essential that we study the past, for we react to the present in a manner which is largely determined by our past experiences.

In order to arrive at a satisfactory understanding of the elements which may have exerted some influence in the shaping and growth of the personality we must inquire into the possible factors which may mold the growing personality. Our first consideration then, most naturally, would be those factors which fall under the category of hereditary influences. These factors, as such, have long been recognized in their potency, and in the present consideration we shall confine ourselves to the discussion of patients who receive an essentially normal hereditary endowment. Second in our consideration are the influences of the environment. The scope of these broaden as the individual gains growth and experience. Included in these, we must recognize those influences exerted by the home surroundings, the schools, the neighborhood, and those produced by the broader social setting as the individual expands his interest and activities.

In the early periods of development of the personality the home stands out preeminently as the

*Address delivered at the graduation of nurses of the United Hospital at Portchester, May 25, 1921.

most important factor. In this consideration we not only must look at the home setting as such, but recognize the various potent factors which may contribute to faulty adjustments on the part of this growing personality in the home. In this field alone the nurse can make a monumental contribution to the health of the home, if she, in her capacity as guardian of the sick, can instruct the mother and father of the child how to meet certain simple everyday problems in a healthy, objective, unemotional manner.

Among the most potent early influences we must recognize the importance of the commonplace events of everyday life, such as the apparently simple problems of nutrition, of sleep, of habits of cleanliness, the ability to accept certain restrictions placed upon them, and the ability to acquire independence. From personal experiences one will be able to see the power for good or evil contained in the possible reactions of the child to these apparently commonplace events and will recognize that they contain elements by which the child builds his progressive steps towards habit formation and behavior manifestations. In other words, the way the child responds to these simple environmental situations predetermines, to a large degree, his future ability or inability successfully to function as an adult.

For example, if the child finds that through the manifestation of fear and sleeplessness when confronted by the dark he can gain the attention of the parent, possibly force the parent to sit by his bed, or lie down beside him, or leave the light burning, he will soon accept this as the most successful way of putting himself across; in other words, he gains attention where otherwise he would not. The same principle can be found in the various reactions to food, his refusal of certain articles, his insistent demand for others. A frequent example of this is the demand for coffee or tea, often a mere transition or continuation of his infantile habit fostered by the mother through her habitual giving of the breast each time he cried.

It is only a step further in this process of maladaptation that one finds the beginning evidences of somatic or physical complaints. We are all familiar with the child who complains that if he is made to eat certain foods he will be "sick at the stomach" and if perchance the parent persists in forcing the ingestion of this undesired food, he soon finds that vomiting of the disliked food becomes the most efficient protest against a repetition in the future. It is evident, then, that even in childhood we may get certain physical symptoms or manifestations as a direct response to certain psychic attitudes. That is to say, if the child finds that he can dominate the situation through somatic complaints, or definite physical symptoms, in this manner avoiding the necessity of making undesired adjustments, he is laying a foundation for future responses, and under the stress of difficult adult problems, he may refuse, or be incapable of facing, responsibilities and may develop an obscure invalidism.

A case in point is that of an eleven year old girl who came to the clinic with a complaint that for the past two years she had been nervous and that each morning she was troubled with an intestinal upset

and vomiting which often made her so weak she could not go to school. The child was evidently dependent upon her mother, cried when asked to enter the examining room, and clung to the mother's hand during the interview. The father was dead; the mother, the patient, and a brother fourteen years of age, lived in a small apartment, the mother earning a livelihood as janitress and washerwoman.

The early history was negative, except that the child was nursed until she was sixteen months old. She had always received a good deal of attention from the mother who was oversolicitous and extravagant in the affection which she showered upon the child; this tendency could be explained on the basis that the lonely woman found, through the medium of her children, a source of emotional satisfaction.

The present nervousness was reported to have begun as a result of fright two and one half years ago, when, while playing in the park, she saw a cousin fall into the pond. The patient cried hysterically for hours, and her present symptoms, nervousness, sleeplessness, nausea and vomiting, gradually developed.

On questioning, it was found that the child had always slept with her mother. She habitually remained up until the mother retired, because she was frightened of the dark. The mother was unwilling to allow the child out of her sight, always accompanying her to school. When the child vomited, the mother became much upset, was very solicitous and more attentive. The child talked freely of her past experiences, of her love for her mother, etc. It was felt that the present symptom complex was largely the result of an unconscious infantile wish to remain with her mother, and because of this, the first step in treatment should be along lines which would tend to free the child from this fixation. The first point of attack naturally would be to assist the mother to gain a new point of view.

This approach met with success. The mother was persuaded to allow the child to sleep in a room alone, to allow her to go to school unattended, to furnish her with certain responsibilities about the house, and above all to help the child become emancipated from her state of infantile dependence. She returned in a week much improved, had had only one attack of diarrhea, was feeling much better, less nervous, and had attended school each day. Four subsequent visits were made, each time with continued improvement, and gradual loss of all symptoms; she had become more selfreliant and independent, to all intents and purposes. She is now enjoying good health.

This case illustrates very well the ease with which a child may become habituated to certain psychopathological means of adaptation and demonstrates the necessity of obtaining a comprehensive understanding of the life of the patient in all its aspects, but especially those presented in the home surroundings. The lesson to be gained from it is even more forceful when we recall that this child had been receiving medical treatment as such, for her physical complaints for a period of over two years.

The frequent occurrence of just such cases in the everyday experience of the nurse leads one to ap-

precipitate the opportunity presented to the nurse in her intimate contacts in the home to assist very materially in the education of the parents and through her insight furnish a powerful means of forestalling these beginning manifestations of maladjustment.

The principle here illustrated is becoming more and more recognized and even in literature it is possible to find concrete examples. In a recently published life of Margaret Fuller, we find existing between the father and daughter a pathological attachment which wrought indelible change, affecting her general attitude throughout Margaret's life. As a result of this profound attachment, we discover evidences of precocious stirrings of sex interests and desires: concurrent with these desires come the conflicting emotions and the attempt on the part of the girl to repress these unacceptable thoughts. It would seem that for some years she was able to do this fairly successfully but when in her twenties, the family removed to a remote farm district where opportunities for companionship were confined to her father, she was able to sustain the emotional conflict for two years and then fell desperately ill, so that even her life was despaired of. This case illustrates very well the tendency on the part of certain individuals to find expression for the emotional conflicts through a displacement of the destructive forces at work to the physical levels. It is in just such cases that nurses may, with a broader understanding of psychological principles, be able to help materially in constructing a healthier mental attitude in these patients, and by so doing free them from the bonds of invalidism.

The third great factor is the influence of organic and functional inferiorities on the personality. Alfred Adler first emphasized the importance of organic inferiorities as the cause of distressing compensatory strivings. We perceive must recognize that inferiorities of an organ or function become emphasized when they tend to cause failure in the competition of everyday life; repetitions of this failure tend to create a fear of failure. The task then is to find a means of adequate compensation.

This is frequently displayed on the physiological level, for it is a common occurrence to find a hypertrophied left ventricle in mitral insufficiency, the enlargement of the remaining kidney when the other is removed or destroyed through disease processes, or the enlargement of the thyroid when the pituitary gland underfunctions, etc.

If such compensation occurs on the physiological level, is it not easy to conceive this process as occurring in the higher psychic levels? As a matter of fact this is just what does occur. In the competition of everyday life, we find certain individuals with recognized inferiorities; it is the fear of their organic or functional inferiority that forces them to make compensation. This is most often true of the functional inferiority which manifests itself in a struggle for heterosexual virility.

Where there exists a condition of sexual inferiority as measured by the sex standards of their associates, such as we find in the effeminate man or the woman with marked masculine attributes, or in those individuals with functional inferiority due to

perverse sexual tendencies or autoerotic cravings, there is prone to exist a "pernicious sense of inferiority from which they are forced to protect themselves in some manner." When we consider the various means an individual may use in seeking to protect himself we find that they may for the sake of convenience be divided into three groups.

First. He may seek protection through avoiding competition. By so doing he need not expose himself to the task of measuring up to the standards of his rivals. But this solution contains within it elements of destruction to the personality, for he may soon find that it is necessary to withdraw from all personal contacts in order to avoid the stressing of his own inferiorities. Through this habitual withdrawal from competitive reality, we find the gradual development of a shut-in personality, with his seclusive suspicious, self-loving tendencies. In other words, there occurs a retrogression toward the deteriorating psychoses. Examples of the end products of this type of defense are numerous in the hospitals for mental diseases.

Second. He may seek for an elimination of this inferiority either through a psychic castration (by this I mean refusal to admit the presence of the offending part), or, as occurs very often, he may seek elimination through actual surgical excision. This type of reaction might be conceived by many as being socially acceptable, for has not the subject of surgical operations become the popular topic of discussion at pink teas and social functions of all kinds?

Not long ago, in discussion with an eminent physician, the statement was made that at least sixty per cent. of the surgical operations were performed in cases where the symptom complex, while apparently due to physical causes, was in truth due to the unconscious affective cravings of the patient. If we accept this as the existing state of affairs, it is easy to see why nurses and physicians should have a thorough understanding of these mechanisms in order that they may better understand the true condition of the patient. It is a common occurrence for patients to return after a surgical operation complaining that only temporary relief was gained and that now they are worse than ever. How can we expect cure when the root of the trouble lies in the maladaptations of the individual in his emotional life? A case which illustrates this point is that of a girl of thirty-two, well educated and holding a responsible position. Two and one half years ago she began to complain of extreme discomfort after eating and showed all the cardinal symptoms of a gastric ulcer. She was cared for by one of the best internists who treated her for gastric ulcer according to all the modern methods of medical treatment, including the use of the duodenal tube for two months. Little improvement resulted and finally he advised a change of scene, restricted exercise, a special diet, etc. A year and a half later she came to me complaining of excessive distress and nausea, gastric pains, and loss of weight. An examination showed extreme tenderness and rigidity over the pylorus. The history of the girl showed many evidences of a neurotic makeup, with an extreme fixation on her father, severe conflicts about certain

friendships, and a recent disappointment due to the unhappy ending of a love affair; in other words, there were evidences of profound affective cravings which were essentially unfulfilled.

I placed her in the care of an eminent surgeon for observation. His first impression as the result of a brief examination led him to believe that surgical intervention might be needed, but careful study for ten days in a hospital, with the use of all the modern methods of diagnosis, failed to reveal the presence of any pathological condition. The stomach contents were normal, digestive functions were normal, the x ray showed no retention, thickening, or any findings suggestive of trouble. Through psychoanalysis, she gained much selfknowledge and as a result of this was able to reconstruct her attitude towards life, so that she accepted a more objective viewpoint regarding the painful repressions, etc., and became finally a well integrated individual. Concurrent with the unfoldings of this selfknowledge, the gastric symptoms disappeared, and she now eats anything she likes and feels like an altogether different person.

We all can learn through illustrative cases of this sort that surgical procedures may not furnish the medium of cure in all cases. Frequent reports of such cases are made. Dr. Jelliffe in his publications reports the case of a man with a sex inferiority which was much overcompensated giving rise to affective tensions resulting in the production of a duodenal ulcer.

This naturally leads me to the consideration of the third type of defence, that of compensation. This is by and large the most frequent and most often successful. By the development of a protective superiority in some other function, the individual is able to gain satisfactory social recognition; if, however, we deprive this individual of his means of compensation by forcing him into a vocation he dislikes, or by preventing him from giving up work that deprives him of a means of solving his affective craving, we drive him back to the realization of his inferiority and then he is prone to become "a patient complaining of distressing cardiac, respiratory, gastric, intestinal or genitourinary symptoms, resulting from an unbalanced and pathological tension of certain autonomic segments."

As Kempf so well states: "These tensions are conducive to unbalancing the reciprocal relations of the segments of the (vegetative) or autonomic system and, by their causing a stream of distressing sensations, force the individual to make a social adjustment. For example, when an artisan loses his right hand in an accident and complains of insomnia, loss of appetite, a sinking feeling in his abdomen, we know that the stomach and viscera in the epigastric region have assumed postural tensions that are the source of a stream of fearful feelings, as he compensates by developing efficient skill with his left hand the dangers of failure and poverty decrease, and the troublesome tensions are relieved. Thus it will be seen if the individual finds a successful means of compensation, he makes a successful adjustment, but when for any reason his means for compensation of his inferiority are removed, he is driven back upon himself, and as a

result of the autonomic tensions set up, he will display a variety of symptoms which we know as physical."

This holds true throughout life. It is a common occurrence to have a child complain of headache when it is time to go to school in the morning, and when nine o'clock has passed the symptoms may gradually disappear into thin air. If, however, one will investigate, it will frequently be discovered that a written test was due which the child feared, or a competitive drill of some sort was scheduled which would force the child to measure himself in competition with others, with the fearful possibility of finding that he would fail to measure up or be unable to put himself across according to the standards of his classmates. If perchance he should, through painful past experiences, have known the dissatisfaction of defeat, the situation is aggravated. Thus it will be seen that the somatic symptom complex has as its basis this driving fear of failure; failure, with its consequent insult to the ego, which, for the comfort of the individual, must be protected.

To give medicine for the distressing symptoms of headache or nausea will not eliminate the basis of trouble. What the child really needs is help in facing difficult situations and in order that he may be better able to do this, we must help him to gain a better mental attitude by teaching him to recognize his assets and his limitations, to accept them as such and to make the most of the equipment which he already has, by finding successful means of adaptation to the realities of life as he finds them.

I have attempted to suggest to you in this brief presentation some of the possible factors which tend to contribute to the shaping of the growth of personality; first, the influences which are exerted from the conception of the individual as a unit, the possible influence of heredity; secondly, the influences of environment in all its aspects, through the medium of the home surroundings, the school, the neighborhood, and the broader community influences met with as the individual expands his social interest and activities. Thirdly, I have presented briefly those factors rising from within the individual himself which tend to bring about changes or adjustments in the personality makeup as such, first through the avoidance of the stress of competition through fear of failure in the measuring of himself with the standards of his associates, secondly, through the refusal of recognition of the offending difficulties or through the attempt to rid himself of the offending inferiority through actual surgical intervention, and lastly, through an attempt to solve his difficulties by compensating for the inferiority through the development of an acceptable superiority.

It is my desire to assist you to gain a viewpoint which will enable you to appreciate the fact that through this psychological approach, you have a definite approach to the physical; that it is never possible to dissociate absolutely the mental and physical elements in any given case; that this interrelation of mental and physical must be accepted, and in order that we may gain a satisfactory understanding of it, a knowledge of the psychological elements at work in each human problem is required.

Personality in the Making

By WALDEMAR H. GROSZMANN,
Plainfield, N. J.

We all have a warmly personal feeling of self which is the mainspring of all our actions, thoughts and emotions. This is the ego. The ego finds its expression primarily through the exercise of our instincts which represent within us the heritage of human as well as of all other life since the beginning of time. We have long recognized that life centres about the operation of two all important instincts—that of selfpreservation and that of procreation. The first seeks the welfare of the individual, the second that of posterity. The instinct of selfpreservation, with its many collateral, supplementary and dependent instincts to reinforce it, and that of procreation, with which are combined innumerable other instincts whose manifestations can either be raised to the highest ideational spheres or be dragged to the depths of grossest animalism, exist in different relative combination and strength within each one of us. The ego is the resultant expression of this distinctly individual complex. To these primary evidences are added those secondary ones which result from the ego's struggles to preserve its identity in the face of the ceaseless onslaughts of the external forces in life. Those expressions of ego resulting from the instinct complex are thus due to heredity; those modifications in the assertions of the ego which result from the struggle for acceptance are due to environment. The life of each of us is a series of efforts to reshape the ego of heredity into forms acceptable to the world of environment. This is indeed a life task, for the original ego is exceedingly tenacious and active in its own behalf to preserve contact with the world outside free from all restraint. To accomplish this end, it will surround itself with an astonishing array of disguises, tricks and other devices intended to deceive the self and the world about.

From this we may infer that the ego labors. First of all, from its earliest beginnings the ego, through its instinct complex, strives for conscious recognition of its existence by the individual. During the early stages the baby is an almost unconscious, plastic medium. Through the very fact of this struggle for conscious recognition, we recognize that by far the greater part of the ego always exists in the unconscious part of each person's psychic life. It is the initial state out of which all forms of the ego must emerge. Such forms of the ego as do finally receive conscious recognition must then be still further modified and curtailed before the prudent individual allows them to meet the eyes of outsiders. In fact, only a small portion of the conscious ego is ever permitted an external life.

For purposes of convenience, let us consider unconscious and inner (that is, outwardly unobserved) conscious life as subjective phases of the psyche, while all evidences of consciousness, whether originally conscious or unconscious, which take form in an external object, we shall consider as objective

phases of the psyche. We shall find that it is the constant aim of the ego to externalize its identity, preferably by way of the inner subjective consciousness into which it has gained admission, or directly from the unconscious into the external if the resistance to even the briefest flight through inner consciousness is too great. The latter is usually resorted to only when immediate external action is needed to meet an emergency through a powerful assertion of the ego in the interest of selfpreservation or when pathological mental conditions exist.

It will have become clear from this conception that the ego struggles against certain restraints which threaten its free expression. Such restraints do definitely exist. They are most easily thwarted in youth, but become more definite and closely interlocked as we grow older. On the one hand they form the basis for mental health, selfpoise, personality; on the other, lack of these restraints explains all the varied and heavily disguised forms of psychic abnormality encountered in such profusion throughout the human family.

These restraints arise from two sources: one of them external to the individual, the other internal. At times they work together; again they will work independently; and not infrequently they will work violently against each other. We are here particularly interested in the psychic restraints.

Let it be emphasized here for purposes which shall become clear in later writings that it is in youth that the barriers between unconscious, inner and outer life are simplest, and that, therefore, the strivings of an active and turbulent ego for objective life are easiest of attainment. It is during these earliest years that the ego wins repeated epochal victories over all psychic resistance—victories which stand out as fixed points in the individual's evolution and from each of which will radiate new lines of conduct which will determine the whole future course of existence in health and in sickness—be this physical, mental or emotional.

What, then, are these psychic restraints, and wherefore the need of struggle?

Who is there who has not at some time felt that he is of better and finer clay than that common to general mankind? This feeling is normally felt most frequently in childhood and early youth, but even through maturer years it is likely to crop out at strange and unexpected moments. Ordinarily, however, as we grow older and realize our shortcomings, as we compare our individual attainments with the even better attainments of others, as our mental horizon broadens through contact with our fellowmen we seek to repress this feeling of smug superiority and strive to content ourselves with a more modest estimate of self. We laboriously train ourselves through systematic and cumulative intellectual discipline to accept the abstraction of reason that we are truly but a single and unimportant phase in the human cosmos of the ages. But we far from

accept this verdict of intellect in our emotional appraisal of self. Here, under many disguises, we continue unto death to believe firmly that we are of the elect in the human family.

That this feeling is normal is evidenced by the fact that we all confess it at some time in our lives. Selfdiscipline, especially when accentuated through fear of ridicule by others, may lead us to hide this feeling completely from the world. But it is only hidden, buried in the deepest recesses of inner consciousness. Even here it is not long permitted to parade in its nakedness before our mental vision, but is pilloried, clothed, and then put to useful work.

The suppression, disguises and work to which we subject this irrepressible feeling leads to many strange variations in the normal life of mind and emotions, and produces within each individual an outward guise or pose which we sometimes call personality. Commonly we associate the idea of personality, not with the neutral aura of average persons, but rather with the striking individuality of persons of distinctly greater intellectual or other attainments than common, or even with mentally peculiar, erratic, abnormal or deranged beings. Nevertheless, the same processes which bring out striking personalities underlie the life of those of us who are average. Everyone possesses personality, but, as we shall learn later, most of us definitely prefer to be average and to regulate our lives in accord with that aim. Average personality, transplanted into strange countries or into other times, would clearly appear to be anything but average to the regular people of those countries or times. They would be like pictures taken from their conventional frames and placed into strange or incongruous settings.

Let us recall the statement that the feeling of a superior quality of our personal clay is felt in its purest form in childhood and early youth. After these early years the feeling is more and more suppressed and mutilated through the conflicts with the ego.

Human society has always realized the existence of conflict between the ego and the world outside, although it cannot be said to have realized this condition in an analytical sense. It has at all times definitely striven through teaching to conciliate the individual and the social group for their mutual advantage. Where it cannot conciliate, society firmly restrains excessive egoistical tendencies. Even in the simplest social organizations a definite course of initiation into family and tribal customs was prescribed for its youth. The individual was taught through religious ceremonies, folklore, ceremonials of tribal organization, customs in hunting, in the use of weapons in warfare, etc., just how to conduct himself, not merely to meet the various demands and exigencies of life for his own protection and advantage, but to meet them according to acceptable standards of conduct. We realize today that even the most obscure religious and other rite ceremonials of ancient peoples originally had basically no other object than to teach youth the acceptable use of its instincts of selfpreservation and of procreation—acceptable to the standard requirements of that social group and time. In

the civilized communities of today we have an even more complete and thorough, though considerably less obvious and direct, education for our youth, calling into service the facilities of family life, a complicated social order and a paternal government.

Thus the first steps in the rules of life are gradually unfolded to each child through some form of systematic external education and restraint. These rules form but a framework for conduct, it is true, but this framework represents a good model. It epitomizes human effort through all stages of its evolution. With this model as a guide, each individual may construct the framework of his life over which he may then cast the mantle of his own personality which shall be woven out of the varied material brought together by his ego.

While external education may proceed according to plan, the individual must begin an adjustment in his inner consciousness practically immediately on the heels of the ego's first defeats which have followed its turbulent stormings into consciousness and the instant conflict with environment which an overflow of this unrestrained ego precipitated. From infancy he is made to understand that his ego and the environment clash in almost constant conflict and that the outside world has an advantage in resources and authority which cannot be gainsaid. Thus the conclusion is forced upon him that, to reduce conflict with environment to a minimum, some definite control to hold the assertive ego in leash must be devised.

The normal healthy ego must of necessity develop into a fighter in order to establish its identity objectively; but it must learn to fight according to certain rules which are sanctioned by the outside world, otherwise it must suffer the penalty of ostracism. Then, like every accredited fighter, it will thrive through training, abstinence and struggle. Not only must it fight according to the rules, but must set before itself a goal, an ideal, which shall be an embodiment of the spirit behind the letter and shall through its distinctive merit give the owner an honorable rating before his audience. Of this the ego is incapable without the aid of definite grooming and control from forces within the realm of subjective consciousness. As this ideal which shall control the ego must make its influence felt before the ego emerges from either the unconscious or the inner conscious phase of the psyche, the latter casts about for a suitable subject within its own domain which shall be enthroned with sufficient power to enforce its dictates.

The realization by the self of this necessity for inner control strengthens the newborn knowledge of the limitations of self which contact of the infant with the outside world has engendered, especially as these conflicts of ego with environment rapidly rise from the level of sensation to those of simple ideation. It affords him the first feeble recognition that he is of other substance than that all about him. The more conflicts he witnesses and the more experience he gains, the stronger and more clearly defined becomes this feeling of separateness, of aloofness, until an exaltation of the feeling of self results. This, as a purely emotional phenomenon, produces a conception of personal separateness from

all things external—the rest of the human family included—and leads from what at first appeared to be only a physical and quantitative difference of individuality to a qualitative one. The emotional exaltation then takes the form of an individual estimate of superiority.

This essentially personal feeling, then, is selected by the psyche to enact, after careful transformation, the rôle of ideal. Through censoring all expressions of the ego which pass in review before it before being allowed out of its control, this ideal shall pass upon or reject what is offered. Its difficult rôle shall be to change the primary ego of heredity into an acceptable secondary ego which shall exist on terms of harmony and cooperation with the environment for the peace and happiness of the individual and of his fellowmen.

The point will here be raised that this peculiar feeling is but a phase of the ego, rather than something distinct; but this is only true in another sense. It is true in so far as the ego adopts the dictates of this ideal as a part of its own acts. To revert to the simile of the fighter: he may be powerfully built, possess great endurance and skill, be well equipped with the weapons of combat, and not only be capable of inflicting punishment but be able to accept severe punishment in return without giving up. But it rests with him whether he shall be hailed with acclaim or with abhorrence, should victory fall to him. The verdict of onlookers will be based first of all upon a common understanding of rules according to which he will be expected to fight. They will then apply this standard to his actions, and will judge him well or ill in so far as he has complied with and lived these rules. In themselves, the rules are an abstraction, an ideal. This abstraction exists outside the individual in the general consciousness of a large group. It is the result of preserving the best experience of the ages. Only in so far as each individual translates this outer general consciousness into terms of his own inner consciousness and stamps with his approval the accepted rules as a true measure of his own acts is this ideal a part of himself. In the same manner the inner ideal is an abstraction which has an existence within the ego only in so far as it serves as an influence on its behavior.

Let us now conceive all individual consciousness, when stripped to its simplest terms, to consist of three phases comparable to a house with three peculiarly built rooms. The first of these is like a dark, unexplored and mysterious cave, a cellar, whose far recesses may, for all we know, extend to the very depths of the earth with its fearsome inhabitants. It seethes with a strange life which is hidden from the light of day. Its forms are inchoate, monstrous, or belong to forgotten ages. Above is a large, half lit room, crowded with furniture and strange beings all in kaleidoscopic motion. Not only do the contents of this room change their relative positions, but at short intervals even the contents themselves seem to melt away and to reassemble in other shapes. Then to our surprise we often note on closer scrutiny that many of the contents which apparently disappeared or changed their form in reality only draped themselves in

clever disguises to hide the original shapes beneath. Thus it goes on incessantly, grouping and regrouping, a partial or complete change of furniture and inhabitants, with new groupings and regroupings, transformations whereunder the hideous assume an alluring covering, while the shy, the beautiful, the wistfully hopeful hide under tenaciously clinging disguises of ugliness and horror—always grouping and regrouping. In spite of this life, this change, this evident rivalry and intrigue and upheaval for favored places, all moves silently. The halflight comes through several small windows which give a view outside. And all this grouping and regrouping, all this restless change, all this fighting for position by force or by trick, have these windows and the two doors in this room as their pivotal points. All strive either for vantage positions to reach one in particular of these two doors, or, as next best, to reach the windows to catch fleeting glimpses of the outside before the next change. All frantically avoid proximity to the remaining door, and can be made to near it only when strength fails under the resistless pressure of the moving mass. The third room is light, airy and amply large for its few inmates. Except where joined to the second room, and except for a roof sufficient to cover the floor space, it is open on all sides. We may think of this room as a porch. Out of the connecting door leading from the second room come strange people, mostly in conventional garb, who either loiter contentedly beneath the shelter afforded by the roof or, glad of the freedom from former discipline and confinement, wander from this sheltering roof forever. They join the increasing throng which seems to spring up on every hand from numerous similar little houses about, all bending their steps toward a common meeting place ahead.

Thus let us conceive individual consciousness, and now let us follow further some of the strange details which this picture has visualized for us.

Up out of the dark, underground room (the unconscious) rises a stairway to the door leading into the halflit room above (inner consciousness). Within this upper room all motion (or processes) of perception, imagery, ideation, are normally under definite control. Not only the motions, processes, groupings and regroupings, behavior and transformations of all things within this room, but the door of ingress from the cellar and the door of egress to the porch are under the control of a guardian—the censor. He it is who opens the door a crack in answer to the summons from below, who passes upon the fitness of some new appearance of the importunate ego to enter, or slams the door upon it if judged undesirable. He it is who enforces the rules within that halflit room according to which that house is to be run. Then, too, it is he who jealously guards the door of egress into the open, allowing none to pass that fail to satisfy him as to their worthiness to act as representative products of his training when they reach the outside. Thus it is normally.

Onslaughts from below often disturb the motions above. Intrigues and deceptions above lead to occasional uprisings against restraint, resulting in

fierce struggles for mastery between inmates and guardian. Such diversion of attention or actual inefficiency on the part of the guardian may result in complete momentary or even permanent overthrow of restraint and a bursting open of both doors. Then follows an orgy of lawless upheaval from below, a storming of the room above, and a headlong *melée* which debouches upon the open porch and into the free world outside. The ego in all his most undesirable forms is rampant, and, unless order can be promptly restored, the strange house is ruined and ready to collapse.

Thus we see why it is fitting to consider the unconscious and inner consciousness as subjective phases of the psyche, whereas those phases which have passed beyond the control of the censor and find their existence in the external world are objective expressions of the same. Actions, thoughts, emotions, feelings or other evidences of self which have once passed or escaped the censor and have externalized themselves are beyond the further control or influence of the individual. Only the effect of their entry into the outside world can be observed, and, eventually, valuable experience is gleaned from this observation which will be reflected in the censorship of further releases.

And it is this very evaluation of experience from the unrecalable acts of the self which are of such inestimable value for the future control of the individual. In infancy, when the censor is practically missing or inexperienced, the door from the unconscious into the inner conscious is open and unguarded. The ego stalks through in whatever form he pleases. He needs no disguise. As the need for control becomes evident, censorship asserts itself in unmistakable terms which become increasingly strict. Then we observe that the ego resorts to wiles and deceptions to gain admission. Further, we note that at certain times, which we now recognize as distinct developmental periods, the onslaughts by the ego become more concentrated and powerful in their pressure. The ego assumes forms with which the censor is so unfamiliar that he is frequently misled into admitting them upstairs without proper credentials for their object or behavior. Only experience will make him more wary for the future. At times the struggles between some new phase of the ego, as it emerges from the unknown, and the censor are so severe that both suffer cruelly from wounds that leave lasting deformities and scars. This battered form of the ego becomes stultified, fixed, and will remain for years hidden in some recess of the cellar or of the upper room, suppressed or forgotten. Then unexpectedly it escapes control when the censor has his attention diverted or is worn with the struggles on every hand. The deformity becomes the source of evil contamination for all the other forms of our mental life. This mutilated form serves as the actual basis of some deepseated neurosis.

As with the doorway between subjective phases of consciousness, so, too, with the doorway leading from inner to outer consciousness. In infancy it is wide open at first. The ego, whose constant aim it is to emerge from the unconscious into objective expression, passes through both doors of the

upper room as if borne on the wings of a draft. Externalization is quickly accomplished. Quick demoralization and death must follow unless at least the outer door is speedily closed.

Let us now look more closely into the evolution or transformation of the superior clay feeling for identity—a transformation which must take place before the rôle of guardian or censor can be effectively established. We wish to discover how, as a psychic phenomenon, censorship is enthroned and develops an existence distinct from the ego it is to control.

Very evidently this transformation results from the interaction of forces exerted both from within the individual and from the world outside. As the feeling of selfappraisement gradually develops it is accompanied by feeble experiments whereby simple modifications of the primary ego are thrust outside for the purpose of checking up the conception of separate entity. Accumulating sense perceptions serve as the basis for simple ideation. Ideation, in turn, serves as the means of orientation as to which of these simple modifications are acceptable outside and which must in future be suppressed. Outside censorship having promptly made its presence known, it becomes clear that future experiments will prove disastrous unless the restrictions and the demands upon the externalized ego are understood. Otherwise the feeling of self becomes so confused in the din of strife between ego and environment that ideation and rationality cannot develop (as we observe in cases of feeble-mindedness, idiocy, and other abnormal states).

As a matter of fact, the outside world soon assumes the initiative in making known its rules, not waiting for ego experiments to make their appearance. A very comprehensive system of information about and enforcement of its schedule of restraints and rules is made known to the individual according to which his censor shall in future be guided before the ego emerges. As indicated in another place, this system or code for conduct is presented in the shape of formal instruction undertaken by various agencies of the social group in which each lives. As we observe how social standards have emerged from their simplest forms to the higher ones of the present day, we note how experience as it has confronted countless individuals in various life situations has been absorbed within a general consciousness common to the entire social group. The lessons of this experience are so preserved as to make it possible to easily teach them to each rising generation.

We may thus conceive that the outside world has developed, first, a social conscience which is a composite conception derived from experiences and observations demonstrating that, whatever line of human endeavor may be under consideration, success for the group depends upon holding the individual to strict adherence to a correct and high level of action. This level is what we may call the group's idealization of its composite self for which it will strive in terms of accomplishment and morality for the common good and in its relations with other social groups. Then we may conceive further that this idealization for the group will pre-

scribe certain standards in accordance with which the actions of each individual member shall be measured. In other words, his degree of conformity or nonconformity to the rules of the group ideal will be tested under a censorship. This censorship we recognize under the name of public opinion.

Group experiences upon which rules are founded fall under different headings which correspond to the principal types of human activity. Therefore, the teaching of these rules for individual conduct likewise falls under subject heads corresponding to group experiences which involve either social organization or control or evolution, etc., or religion, intellectuality, business efficiency, etc. Thus the individual is coached in the rules of community life, of political government, of business cooperation, etc.—eventually even to the extent of acting as an all rounded representative and mouthpiece for his social group in establishing relationship with other groups. The young and growing child learns his first systematized rules mainly through family precepts, playing with companions of his own age and through a lengthy formal scholastic education. Whatever phase of the lessons in human experience it may be, each is intended to teach to the inexperienced self the mechanics of inhibition and of correct expression.

That group instruction is in a constant state of readjustment is witnessed, for example, by the history of even the most abstract and formal of these systems, that of scholastic education. Here are illustrated the many changes in the conception of relative values and in the aim which the social group has entertained from time to time as to the proper relation of the individual to his group. We need to recall but a few of the main historical viewpoints to realize their diversity; recapitulistic, practical, disciplinary, humanistic, religious, idealistic, naturalistic, sociological, etc. Each in turn sought to set up a syllabus of rules and aims which, through their retroactive effect, were so to organize individual consciousness as to curb or develop only such activities of the ego as would advance individual welfare in such manner as would at the same time insure the desired group welfare and progress suited to the group ideal for that age. One system would arbitrarily postulate its mandates, demanding implicit mechanical obedience by the individual without caring whether that individual's censor understood or could assimilate the restrictions; another would endeavor to win the cooperation and endorsement of the individual by painstaking explanations; again, one would emphasize certain activities and aims, much to the detriment or even to the exclusion of others; another would place a similar emphasis elsewhere with equal narrowness. Similarly, our social, political, religious and other forms of education have undergone almost startling revisions, not only of the substance of their precepts but of the very objects underlying them.

Today we have broader vision, and the education that comes to us through so many distinct agencies is more harmonious in its aims than in the past. Group consciousness recognizes the value of versatility, of flexibility, of emphasis, particularly upon

those forms of education which not merely curb but help the individual to develop his best self by imparting those rules and aims which the censor most needs. With the greater complexity of community life, the diversity of individual interest and effort, the increasing homogeneity of large social groups through the aid of inventions, improved communications, an almost universal interchange of commodities and ideals, individual censorship receives practical demonstrations of the great bulk of community rules in most divers ways. Vicarious teachings through travel and through the rapid changes in environment are so general that they very thoroughly supplement all merely formal instruction. Examples of the consequences of an ego rampant in a community are thrust upon the attention of the individual censor from every side and make obvious the need and purpose of organized restraint to insure safe and happy intercourse within masses.

Thus in every possible way the censor of the individual is informed about the demands of life as far as these can be taught in advance from outside. Just as throughout the course of history, so, too, in the lives of individuals this training is a continuous process subject to revision in content and purpose as the environment changes. In their highest forms the rules and ideals of general consciousness are definitely codified in written and spoken language and in the language of a varied symbolism, all of which are incorporated in the teachings, customs, laws, ethical morality and religion of the group.

With this training in example, guidance and restraint from without it is now incumbent upon the censor to evolve its own set of rules and aims in a manner similar to the evolution and to the main outlines of this model. We are now prepared to proceed to define the origin and the nature of this individual censor.

The inconsistency of flaunting to the world at large a feeling of individual superiority early becomes evident to its owner as he winces under repeated and drastic rebuffs of his ego. Therefore, to shield this feeling from complete disruption under these attacks, the individual locks all evidences of it within his inner consciousness. Here it is kept hidden from observation from without. As there lurks a danger of an occasional unintentional escape, the feeling is suppressed under a new guise whose appearance is not objectionable to others. The individual now takes the position that he will develop a set of rules for himself beneath whose standards one of his superiority must not stoop. Thus, from a misconception of the meaning of physical entity which the individual first builds up out of the realm of sensation, general perception, and simple ideation, he transforms this feeling to an idealization of self. This idealization of self increases in proportion to his higher ideational emancipation from material conceptions.

Such selfidealization of necessity implies the scrutiny of all acts, thoughts and emotions of the primary ego to compare them with the demands set by the ideal. This is censorship. Censorship serves as the dynamic aspect of the ideal. This dynamic aspect is what external education strives to help into

action by the example of its precepts and restraints. Through the conversion of the earlier inner feeling of superiority and through the retroactive effect of this education from without idealization of self rises out of nebulous stirrings to definite form. As the outlines emerge they remain plastic to contact for a long time and are capable of considerable growth and development.

However, while normally the ideal resembles a living thing with capacities for growth, development and change, such is not always the actual history, for contact with a virulent primary ego and the often hostile attacks made upon it from the outside tend to disfigure it. It is then warped by fixations, mutilations, excrescences, perversions, inversions and other unhealthy conditions which in turn weaken its power of censorship. The psyche is then exposed to maladjustments to life situations which become the precursors of unhappiness and mental derangements.

Just as general consciousness places experiences and their lessons in cause and effect together under various headings in accord with their meaning and activity, so the idealized self soon surrounds itself with certain concepts. These concepts are the foci about which all rules pertaining to that subject are catalogued and upon which the censor relies for guidance. When correlated, these foci in time form the structure known as individual morality.

Among the many such foci which might be mentioned as particularly important is the concept of selfrespect, together with its vital complement, humor. About the concept selfrespect cluster the standards for preserving physical wellbeing, for maintaining mental cleanliness consistent with a sound morality, for insuring mental poise and control, for developing honesty with self in the recognition and appraisal of the primary ego, no matter in what crude form it wells up out of the unconscious. On the other hand, humor is necessary, not merely to help us to see the inconsistencies which exist in the broad world of men and things, but more particularly to enable us to recognize how incongruous some of our own ego transformations appear to others. An unbiased understanding of the oftentimes ludicrous rôles we ourselves play unwittingly, together with a kindly receptivity towards criticism, helps to show us how in future we must mold our ego transformations in better proportions before releasing them to outside view. He who lacks selfrespect and humor as definite and well developed concepts belonging to selfidealization lacks important factors necessary to mental health.

Another focus is the conception that effort must be centralized about certain aims of attainment. This concept we call ambition. Ambition establishes the intensity standard as well as the particular limits within which primary ego forms shall seek suitable secondary expression to insure cherished external effects. The intensity standard determines the degree to which the individual ego shall strive to stand out clearcut in group consciousness.

Similarly the reader may easily select other concepts necessary to a wellrounded ideal of self (such as reverence in a religious garb, ethics suitable to

social or business relations, love in the form of brotherliness, altruism or selfsacrifice). About each of these the ideal of self will group appropriate rules to permit the censor to have a comprehensive control over the ego in whatever garb or in whatever situation it makes its presence known.

We speak loosely of these foci as the individual's various ideals. It would be more correct to say that they are but separate aspects of a central ideal, this very ideal of self. A frank scrutiny of our many different ideals will show us that they are nothing else than standards of measurement in terms of moral values for selfconduct. We understand how to be honest, unselfish, brave, and religious—only to the extent that we have set up an ideal of ourselves and imagine our personal rôle in enacting the rules which we believe to be consistent with these ideals.

Most of us greatly prefer to keep the struggles between our ego and the world outside down to a minimum. This means conserving energies which might otherwise be wasted through diffused efforts in selfassertion on unessentials. Or it spares the uncreative the physical discomfort and the mental travail that high ambition, for example, entails by forcing distinctive ego forms upon a hostile world for acceptance. Equilibrium is easiest of attainment when the group ideal and the self ideal are as nearly identical as possible. Individual censorship then becomes a mere imitation of external restraints. Most of us definitely seek such equilibrium in all ordinary occupations necessary for the pursuit of health, comfort and happiness. In an environment of peace, habit, conservatism, it is not necessary to stimulate high ideational centres to keep this equilibrium serene for carrying on a routine existence. But we must possess a docile ego which allows itself to be externalized in whatever guise is desired without raising an issue. At such times we are simply average in our reactions dormant in effort, in a rut. Stagnation would soon result in any group where all the members continued undisturbed in their pursuit of such a supine existence.

Fortunately for an active evolution, however, few social groups become stagnant nowadays. Even the average person reposes in false security if he depends upon such imitative censorship to suffice in all situations. Even he possesses certain primary ego forms which will refuse complaisance to accept only such secondary transformations as will not conflict with exterior standards. Instead they will struggle obstinately with their censor for recognition on the merits of their distinctive appearance and value. The group is then likely to witness an outburst of individuality which will be duly put to the test of public opinion.

Again, as communities in these days of travel and industrial flux seldom remain constant in membership for more than brief periods, individuals shift about from one environment to another. Group standards vary. Even where this variation is slight, an equilibrium founded upon weak, imitative censorship is in danger of serious tremors with each change. An imitative censor has to have time to discover and assimilate the new rules. Such slight variations accompanying a moderate number of

changes of environment have a beneficent effect on the censor in that it becomes accustomed to readjustments. But rapid and radical changes from one environment to another, such as sudden upheavals in the social order and violent emotional storms, all of which demand immediate reactions to totally different or unfamiliar standards, find such a censor so unprepared to function as to be quite useless. It suffers immediate breakdown and can exercise no restraint during the instant clashes between the new mandates outside and the stampede for the open which is made by the primary ego forms. The old battles must be fought once more before equilibrium can be reestablished. When such loss of control occurs we say that for a time at least the individual has lost the veneer of his civilization. This is sometimes never regained.

But every group has in addition to a majority membership of average citizens, at least a sprinkling of individuals who are not satisfied to be average and who therefore do not conform to group standards simply on a basis of imitation. Through greater selfidealization, which must be prefaced by higher ideation than that needed to meet the immediate demands of environment, such persons develop an inner censorship which shows an increasing independence of outer standards. Through more varied and more mature experience, through the observation of remote relationships, of cause and effect, etc., ideation has enabled idealization not only to rise to greater heights but has prepared the ideal to foresee demands which might suddenly arise. Thereupon the ideal has instructed the censor how to meet eventualities. Thus the individual can maintain equilibrium in the face of radical changes of environment, sudden social catastrophies, emotional strains and any other severe tests with which the censor might have to cope.

We are now prepared to understand that personality is a composite effect which the individual makes upon others, the sharpness of outline whereof depends upon the extent to which idealization has taken place and has demonstrated its dynamic power to censor the primary ego before it is permitted freedom in its secondary forms. Regardless of a common heredity idealization of self and censorship are individual. Only in so far as we can lay bare this idealization and this censorship are we able to understand the relation of individual to general consciousness, are we given a key to each personality. This explains the marked differences in individuality that exists between brothers and sisters, families and communities or nationalities, etc.

From the viewpoint that censorship is the dynamic side of idealization of self, it follows that imperfections or errors in this censorship must be due either to a faulty ideal or to inconsistencies in interpretation causing differences between the idealistic concept and the censor's practical application thereof, especially in the cases of those ego forms which are insistent upon immediate liberation. That these imperfections or errors whatever their cause, are very common is manifest.

Where the fault lies with the ideal itself correction is difficult unless it is merely a question of juvenile immaturity. We have observed that the

ideal is the result of subjective developments within inner consciousness. If an improvement or change is to be effected, this must result from an inner reappraisal of self. In youth such a reappraisal might follow a series of severe defeats at the hands of one's own ego which brought social ostracism or other community punishment as a result. But after childhood and early youth the plasticity of the psyche has diminished to such an extent that such reappraisal is seldom successful or even voluntarily considered. In the adult the psyche as a whole is often unhealthy, abnormal or incomplete. When ego triumphs over a faulty ideal, selfrespect, ambition, honor, love and all other focal concepts upon which a sound ideal should be founded prove themselves in this case to be but shams, substitutions, adulterations. They cannot give the censor the necessary strength to resist the pressure. Either the framework they form for the ideal must be shored up from within by a sudden selfrevelation and be replaced as promptly as possible by permanent and honest materials or both framework and ideal must collapse. In some cases outside assistance may accomplish results indirectly. This is possible when some powerful external example or suggestion can be interpreted by the self to be auto-suggestion. Then the feeling of separateness of self from the outer world is momentarily lost in a confusion as to which is which and in unhealthy minds especially this confusion may persist over considerable periods. More often it is fleeting in character and temporary in effect. Usually society can do little for or with the individual whose unhealthy abnormal or incomplete psyche can unfold only an imperfect selfidealization. Ordinarily it simply takes purely repressive or protective measures in its own interest. It calls such an individual permanently insane, criminally defective, feeble-minded, etc., and seeks to make him harmless whenever he threatens community life with ego forms dangerous to others.

Where the imperfections or errors in censorship are due to a hiatus between a correct idealistic concept and its practical realization into ego action, correction may be more easily effected either by readjustment within or by direct outside influence. The outside world offers its wealth of historic and current examples of concrete idealism. Most misinterpretations of the individual's own ideal may readily be modified by finding the proper prototype already existing outside. The censor has but to search. Where actual pathologies in censorship exist which interfere with the free search for the right prototype, the physician, the psychoanalyst or some other intermediary can usually effect the connection and establish a harmonious relation between the idealistic concept and its dynamic interpretation.

In fact, a very large proportion of the successful corrective treatments of mental cases are due to establishing such harmonious relations. Where no prototype exists the censor, after a possible succession of failures, must await further ideational evolution of the ideal whereby the concept to be interpreted will be clarified. Then the censor may proceed to call into play such ego forms as will execute the required transformations. But the cen-

sor of the ordinary normal person is rarely at a loss to understand what interpretation to put upon his ideal. This is more likely to occur where persons possess special abilities, talents or genius of a creative kind which seek new vehicles of expression.

It is not within the scope of this general presentation to enter upon more than a very brief survey of some of the common defects in censorship based upon errors in idealistic interpretation. Their intensive study opens up the broad subject of the range of types of personality, their variants and their characteristics. It furnishes an insight to practically the entire gamut of psychoses encountered in mental pathology.

Let us revert for a moment to our visualization of the three phases of consciousness. Idealization of self being subjective, we shall expect to find the censor enthroned in the middle room—inner consciousness. Here it creates, struggles and errs, acting as buffer, mediator, advisor and master on the battleground where untamed and uncouth ego forms of heredity meet the hosts of personal and social precepts which would bar the path to their ruthless expression. Therefore the censor to be efficient in exercising his control, should possess adaptability to meet the ego in whatever guise it rises out of the unconscious and should be in instant command of suitable transformations for externalizing each ego phase. Likewise it must possess strength, ingenuity and judgment sufficient to cope with the powerful and strange shapes through which the ego may make its appearance.

Common errors of the censor are those of being too strict, too lax or unstable in interpreting idealistic standards. Excessive severity keeps the door to inner consciousness shut to all but the most docile ego assertions. If perchance an admitted form becomes restive while being shorn and transformed, it is promptly ejected and cast back into the unconscious. The docile forms which remain in good standing become so few and are so regularly transformed into stereotyped patterns that they do not represent the virile ego which is being forcibly relegated to inaction. Painful repressions and distortions are effected by too ascetic, too consistent, too literal an enforcement of the rules. At best, inner consciousness becomes cluttered with multifications and fixations. These in time may accumulate such strength as to offer serious resistance. The upheaval may confine itself to the upper room and be quelled eventually. But not infrequently the censor himself has been chastened with the result that it enters into compromise with the ego. This often seems to be the real history of many a missing person who is discovered in new surroundings under a new name after having suddenly dropped completely out of sight at home without clue or explanation. Censor and ego have agreed to interpret the ideal self anew by making a fresh start. As this could not be effected among the old associations, a new and sufficiently remote environment is selected. Such disappearances are particularly characteristic among adolescent boys and girls who run away from what they deem undue external restrictions. In reality it usually is a wild ego assertion against too strict an interpretation of the

personal ideal. The immediate external incident is but the signal for revolt. In later years under new surroundings, the individual will almost invariably realize that even the external event was a correct interpretation of his own ideal though harshly applied. With a more friendly censorship he will successfully fulfill the very idealistic concepts which at an earlier time caused such upheaval.

Laxity of enforcement of restraints results in admitting disruptive and dangerous ego forms to inner consciousness. Under slipshod censorship these will escape into objective expression in flimsy guises which do not deceive even the censor as to the sinister acts they may immediately commit upon reaching the outside. We say that such individuals are too impulsive. Many of the crimes and other regrettable acts which constantly occur in every community have no other origin than carelessness in censorship due to laxity in applying the existing idealistic standards.

Instability in censorship is a frequent cause underlying peculiar forms of personality. The censor is inconsistent in his enforcement of the rules. At one time he will hold the ego down to rigid restraint; at another he will be almost indifferent how the ego emerges into the world. Or he will emphasize now one rule, now another for the same ego form. Such censorship is characteristic of emotional individuals and is a frequent cause of multiple personalities.

The censor that causes the most startling and varied transformations is the unhealthy one. Strange as it may seem, an individual may have a high ideal of self and at the same time possess a censor that is wholly or partially paralyzed, vicious, corrupt, negative, perverse. The individual fully recognizes the standards of his high ideal, yet is unable to make that ideal function in terms of action in accord with these standards. His ego will be thrust upon the world by the censor in forms wholly at variance with his desires. He will knowingly commit acts which he himself condemns. The reasons for such contrariness and failure on the part of the censor are many. It is possible that the ideal, through purely ideational evolution without concomitant actual graded practice, has left accomplishment in terms of action so nebulous that the censor is helpless to translate abstract rule into concrete act. Again, the censor himself suffers fatigue, loss of strength, weakened resiliency, amputations, scars, etc., through his constant conflicts with the primary ego. This leaves him in serious ill health or even diseased. He suffers amnesia regarding whole sections of the ideal's concepts and their concentric sets of rules. The existence of the whole catalogue of restraints and precepts connected with self-respect, with honor, are forgotten. The individual retains his knowledge and belief in them, will discuss them, yet will be unable to influence his censor to observe them. We see practical examples of this phenomenon on many sides. We recognize selfishness, loss of self-respect, lack of humor, treachery, cowardice, etc., in individuals we know possess the true concepts in well developed form, who have observed them at an earlier period in their lives, but who now do not practice even the most evident rules. This unhealthiness of the censor in time assumes more seri-

ous forms, such as hysteria, dementia præcox, sexual perversions and inversions.

Thus we see that personality, while doubtless influenced in its outward guise by the kind and degree of individual selfidealization, is particularly the result of the type of his censorship. Nor do we judge an individual's personality by the total work of his censor (for this includes his activity in admitting the primary ego and governing conscious life within inner consciousness), but only by the accredited transformations into secondary ego forms which this censor sends out into the world.

In closing, the following résumé may be helpful: We have sought a closer understanding of the evolution of the ego as it wells up in its primary forms out of the unconscious, undergoes transformations within inner consciousness and is then launched into the objective world in guises acceptable to group standards. This evolution involves certain factors whose functions we sought to analyze. From the early material misconception which gave rise to a feeling of the individual superiority of our own clay there develops the idealization of self. This represents a subjective evolution and results from arranging ideational and spiritual concepts in focus for suitable interpretation in terms of ego

transformations. For accomplishing this, the ideal brings into play its dynamic side—the censor. Both ideal and censor are a part of self distinct from the ego they govern. The censor is guided by the definite restraints and precepts grouped about the concepts (or ideals) which form the framework for the ideal of self. These concepts and their rules are the combined result of external example presented to the individual in youth through formal and practical education and of personal ideational evolution. As the idealization of self is a subjective development, it cannot be altered directly through external interference. On the other hand, the censor is a plastic reflection of environment and of ideal of self and is therefore readily readjusted from without or from within when ordinary difficulties in interpreting either community or idealistic standards arise. But the type of censor varies in different individuals, thereby causing differences in the transformation of similar ego forms and also giving rise to inconsistencies between selfidealization and selfexpression. As these variations in censorship are the controlling factors in ego externalization, their study gives us the key to understand the causes of variations in personality.

Pulmonary Tuberculosis in Young Children

By ALVIN E. SIEGEL, M. D.,
Philadelphia,

Lecturer in Pediatrics, Medical School, Temple University; Assistant Pediatricist Methodist Hospital; Assistant Pediatricist Samaritan and Garretson Hospitals; Associate Pediatricist Jewish Hospital.

Marked or well advanced tuberculosis is readily recognized, but attempts to overcome the infection and to prevent its further progress are rendered more difficult the longer the infection has persisted and the further it has invaded the tissues. Therefore, it is of the greatest importance that the disease be recognized early.

Statistics show that tuberculosis is frequent in children. These figures have been generally high, averaging from thirty to fifty per cent. of the lesions found in postmortems. Bradley (1) says that during 1919, 2,207 deaths from tuberculosis in Pennsylvania occurred in persons under nineteen years of age, and that during the same time for the same age period there were 515 deaths in Philadelphia. These figures are not based upon autopsy findings, but upon the clinical diagnosis of the cause of death. They, therefore, probably represent only in part the entire number of deaths in which tuberculosis was present.

Cooke and Hemplemann (2) describe as a separate clinical type masked juvenile tuberculosis, which they think is sufficiently distinctive to warrant a position in the classification of tuberculous affections of childhood. The characteristic clinical picture shows a history of frequent coughs and colds, attacks of unexplained fever, anorexia, loss of weight and asthenia, and apathy. Physical exami-

nation reveals more or less evidence of malnutrition, anemia, manifestations indicating involvement of the tracheobronchial nodes, and usually some variation from the signs elicited over the normal lung. There may be phlyctenular disease or tuberculides. The von Pirquet test is positive, as are also the intracutaneous tuberculin tests. In children past the fourth or fifth year seventy-five per cent. give positive complement fixation tests for tuberculosis. X rays often reveal unsuspected lesions in the lung tissue, as well as involvement at the hilus of the lymph glands. The diagnosis is based upon a consideration of all these points.

The routine examination of all children in the Children's Clinic of the Samaritan Hospital has revealed a frequent incidence of incipient, masked, and frank juvenile tuberculosis. Except in the latter type improvement has followed simple therapeutic measures, especially hygienic and dietetic care. These results seemed sufficiently constant to warrant calling attention to the benefits to be derived from early recognition and treatment in the first two classes of cases. A few illustrations are offered.

CASE I.—J. I. H., aged nine years, presented an example of easily recognizable variations from normal that were not recognized because there had never been an examination of the chest. On ac-

count of the child failing to improve under treatment, a former patient of the Samaritan Hospital recommended that he be brought there for removal of his tonsils and adenoids. He was a mouth breather, had occasional sore throats, but frequent coughs and colds. He was backward at school and at play, and was overmodest. He had whooping cough at twenty-two months, and had also had chickenpox. The father and mother were both living and well. There was one sister living and well, and one brother, who had been badly burned some months before. Physical examination revealed that the tongue was clean and moist. Several teeth were missing, and one was carious. The tonsils were enlarged, especially the left. The chest was long and thin, expansion poor but equal, with resonance slightly impaired over the right side both anteriorly and posteriorly, and over this area there was some roughening of breathing with prolongation of expiration (bronchovesicular breathing). Tactile and vocal resonance were increased, while over the left side the sounds were normal. The heart was slightly enlarged to about three cm. to the left of the mid-clavicular line, the sounds were of poor tone, and there was an inconstant systolic murmur at the apex. There was a marked phimosis. In view of the physical findings it was deemed inadvisable to have the tonsils and adenoids removed, and it was recommended that dietetic and hygienic measures be followed until the pulmonary condition might permit of operation.

CASE II.—R. V., aged seven years, presented another illustration of this type of case. He was brought to the hospital complaining of a cold, which had persisted for more than a week. He was unable to sleep on account of coughing, which was continuous. The cough was dry; there was no expectoration. He had had a similar cough every winter. He had some coryza, and his mother thought that he had some sore throat. His bowels were regular. He had mumps in 1920, but had had no other illness. The father was living and well. The mother had a similar kind of cold. There was one sister living and well. The patient attended school.

Physical examination showed that his tonsils were enlarged, the nares were occluded, several teeth were missing, and several of the permanent set were erupting. There was enlargement of the cervical lymph glands. The tongue was clean and moist. His posture was stoop shouldered, scapulae prominent. The chest was poorly developed and nourished. Expansion was poor but seemed equal. The lungs showed impaired resonance amounting practically to dullness over the greater part of the right lung, and over this area there was increased tactile and vocal fremitus with roughened breathing and prolongation of expiration or bronchovesicular breathing. The left lung seemed normal except for a slight variation from normal resonance. The rate of the heart was increased; no murmur was heard; the second sound at the apex was accentuated, the tone was fair, and there was no evidence of cardiac enlargement. The nose and throat department reported that there were large irregular tonsils, with the nares partially occluded with mucus. The breathing space was fairly clear, although there was

a good sized mass of adenoids. An x ray of the chest showed no evidence of tuberculosis. After treatment at a later period examination of the lungs showed that the signs were clearing up. He seemed much better. His color had improved, his face was fuller, and he had gained in weight. The only complaint was night sweats.

CASE III.—P. W., aged six years, who was brought to the clinic complaining of a cold which had existed for about a week, presented another striking example of this type of involvement. There was considerable cough, with expectoration of a light colored fluid, which was worse at night. He had been subject to frequent colds, and was usually constipated. He had had measles at two years, whooping cough at four years, and no history of any other illness except frequent colds and tonsillitis. He had been under treatment in the surgical dispensary for a laceration of the head, which had no bearing on the complaint for which he came to the children's clinic. His father was living and well. His mother was under treatment in the medical dispensary for diabetes. Four brothers and three sisters were living and well. One brother was under treatment at the Naval Hospital for stomach trouble. The child spoke with a decided impediment of speech, and was understood with difficulty.

Physical examination showed that his nares were occluded, and the tonsils greatly enlarged. The tongue was coated, and there was some cervical adenitis. The chest was thin and lacking in subcutaneous fat, but the muscles were well developed. Expansion was poor at the right apex, there was dullness both anteriorly and posteriorly over the right lung, and anteriorly the dullness was accompanied by increased vocal resonance. The breath sounds did not seem to be increased, but there was some prolongation of expiration, and sonorous râles were scattered through both lungs. The von Pirquet test was negative. X ray showed extensive adenitis at the right hilus, indicating incipient tuberculosis of the right lung. Under treatment his general condition improved. He became brighter, more active, had a better appetite, and began to gain color and weight. After a few weeks the signs in his chest began to clear up, although they persisted for more than a month more. After this time his lungs seemed normal, he had no cough, and there had been a marked improvement in his general health so that his condition seemed to warrant removal of the tonsils and adenoids.

The cases already cited were either examples of incipient tuberculosis or probably of pretuberculous manifestations. They are only a few instances taken more or less at random from a number of such involvements that have been observed in one of the three divisions of the Children's Clinic. A case, which was under my care in another institution, so well illustrates the type of masked juvenile tuberculosis that I feel justified in adding the history to this presentation.

CASE IV.—The patient, a boy, C. L., aged five years, was brought to the hospital for weakness and fever. He was admitted October 5, 1920; since September, 1919, he had not been well. At that time he had an illness which had been diag-

nosed as typhoid fever both clinically and from positive Widal reactions. After this illness he did not gain as he should have. In May, 1920, he had another somewhat similar illness which was diagnosed as paratyphoid fever by laboratory findings. Since these illnesses he had been very weak, had poor color, no appetite, and was very apathetic. He was rather constipated. There was no cough, but he frequently had colds. Tonsillectomy and adenoidectomy had been performed two years before. The fever which he showed at the time of admission occurred from time to time. Just prior to coming to the hospital it had been associated with considerable and definite rigidity over the gallbladder region. His past medical history was negative except as already set forth. He had never had any of the diseases of childhood nor any other infectious condition, such as influenza or pneumonia. Examination showed a pale, weak looking boy, who seemed apathetic and undernourished. No gross deformity could be noted except a slight lateral curvature of the spine. His head was negative, but the face was pale and thin. The tonsillar bed was clear, but the pharyngeal wall was fibrous and rough in appearance. The cervical glands were palpable, but not greatly enlarged. The posture was somewhat stoop shouldered. The chest was thin and poorly nourished, expansion fair and equal. The clavicles and scapulae were prominent. Percussion showed little or no variation from the normal. There was some roughening of breath sounds over the left apex and the right base, but no râles or other adventitious sounds were heard. There was apparently no enlargement of the heart, and the sounds were of fair tone. The cardiac rate was rapid, but no murmur was heard. The abdomen showed some lack of tone of the large muscles. There was no apparent enlargement of the liver or the spleen, and there was no rigidity or tenderness over the gallbladder region. No tumors or masses could be felt. The extremities were thin but were otherwise normal.

Five days later examination of the chest showed that there was a slight increase in vocal resonance at the left apex above the posterior scapular spine. There was slight bronchovesicular breathing. There was no sense of resistance or tenderness over the lower rib margin or over the gallbladder area. The condition remained the same for more than two weeks, there being a temperature range between 97° and 100°. After this period subsequent to catching cold the temperature rose to 102°, fell to 100° and rose again to 104°, after which it ranged irregularly from 98.6° to 102.6° for nine days. After five days of normal temperature there was another flareup and a period of normal temperature for sixteen days followed by another similar flareup, on the subsidence of which he was discharged.

Beginning with this febrile period his physical signs changed somewhat. There was increased dullness at the right apex, especially in the first interspace, shading into an element of resonance at the third space. The breath sounds over this area were not increased. Dry râles were heard all

over the chest. Just prior to discharge physical examination showed dullness over the right apex anteriorly from the second space upward; posteriorly the note was impaired over both apices, but more especially over the right. The breath sounds were distant over the right apex; dry, sibilant, and sonorous râles were heard all over the chest. The voice sounds were lessened over this region. Laboratory studies were made. Examination of the stool for tubercle and typhoid bacilli was negative. Blood examinations showed red blood cells 4,990,000; white blood cells 22,300, hemoglobin eighty-five per cent.; polymorphonuclear leucocytes forty-seven per cent.; small lymphocytes forty-eight per cent.; large lymphocytes two per cent.; transitionals three per cent. Blood smears were negative for the plasmodium malariae.

The first Wassermann test was reported as doubtful, but another made a week later was negative. Many attempts were made to collect sputum for examination but without success. The von Pirquet test was positive. The x ray studies were interesting. The first made a few days after admission showed consolidation of the upper right apex. It was impossible to tell whether this was fluid or a mass as in unresolved pneumonia. A week later the x ray findings were that the condition remained much the same, but the mediastinal glands at the right hilus were more enlarged. Two weeks later it was reported that the upper right lobe was still thickened, and the mediastinal glands were still enlarged. This area of consolidation or fluid seemed to be gradually lessening in density. A final x ray was taken previous to discharge. This showed about the same conditions as in the last examination. After going home the improvement in the general condition was progressive for about four weeks, when he was seized with another febrile attack with an acute cold and cough ushered in by vomiting and associated with marked abdominal tenderness and rigidity, this time over the appendiceal region. Appendicitis was so markedly simulated that the attending physician felt inclined to operate. After a few days the attack subsided and the abdominal symptoms disappeared, and after a short time the cough again improved.

The child was seen a few weeks ago and his general appearance showed a marked improvement over his appearance on admission. The physical signs still remained much the same as at the time of his discharge from the hospital. The improvement in his general condition was, however, very apparent, in his good color, round face, well nourished body, animation, and happy expression. This case is not to be considered as terminated. Care and observation must be practised even past the years of adolescence and well into adult life. There was here a latent, or perhaps more accurately speaking, a masked focus of infection which became activated as a result of an acute catarrhal infection.

Hyperchlorhydria in Childhood

By L. BERMAN, M. D.,
New York

Associate in Biological Chemistry, School of Medicine, Columbia University

There occurs in childhood, most frequently during the period between the termination of the first dentition and the beginning of the second, a symptom complex or syndrome referable to a disturbance of gastric function, secretion and motility. The symptoms, one of several of which may be present, are 1, disturbance of appetite, 2, abdominal pain, 3, nausea and vomiting, and 4, constitutional symptoms. Because of good therapeutic results, obtained by the elimination of dietetic irritants and poor feeding methods and the giving of alkaline antacids, these cases have been ascribed to hyperchlorhydria. Thus Hutchinson (1) refers to the case of a little girl who complained of abdominal pain shortly after meals, which was relieved by carbonate of magnesia. He supposed the pain was due to overproduction of acid, and he believed that such cases were uncommon.

Early in the history of gastric analysis M. Rosenthal, of Vienna, published, in 1887, a paper on hyperacid vomiting and its effect upon the urine, and reported that in a number of children between the ages of seven and eleven, suffering from paroxysmal vomiting, the vomitus was hyperacid, and that at the same time the urine showed a decrease of chloride. He refers to a previous work of Rossbach in 1884 describing a condition of gastroxynsis, occurring in young neurotic school girls, characterized by paroxysmal vomiting and hyperacidity. In 1885, Teppe described a similar condition as gastroxie.

In 1897, Soltau Fenwick (2) described paroxysmal hyperchlorhydria as a cause of abdominal pain in children. He cites cases in which abdominal pain occurred, with vomiting, preceded by headache, manifested for the first time at the age of four. The vomitus acidity was 0.45 to 0.52 per cent. of hydrochloric acid, the normal being about 0.2 per cent.

Most of the work done since has been on the gastric secretion of infants. The majority of observers are agreed that the amount of free hydrochloric acid in early infancy is very small, in fact, often *nil*. Thus the investigations of Sotoff showed that in early infancy the total acidity of the gastric juice was 0.02 per cent. forty minutes after suckling and 0.08 per cent. eighty minutes after suckling. Most of this is due to fatty acid, free hydrochloric acid being about 0.0088 per cent.

Hahn found the acidity of the gastric juice in infants, as expressed in terms of hydrogen ion concentration, to be 1×10.5 at the height of digestion.

McClendon investigated the change of hydrogen ion concentration of the stomach in the adult and infant during the progress of digestion by lowering a hydrogen electrode into the stomach. By taking quarter hourly readings, he found that the acidity of the adult stomach rapidly rose during the first one and one half to three hours after a meal, after

which it remained stationary until the food had left the stomach. In an infant, in the first month the acidity rose slowly during the first hour, but after that it rose rapidly; four hours after nursing it might be as high as in the adult.

The occurrence of hyperchlorhydria in infancy was described as an unusual condition by the French observers, Oddo and DeLuna. They described eight cases of hyperchlorhydria in infants of four months, seven months, eighteen months, nineteen months (two cases), twenty and twenty-one months. All these infants were dyspeptic. They showed hyperacidity varying between 0.148 and 0.475.

Knoepfelmacher, a German, described a case in a baby girl of ten months in whom at different examinations the free acid varied from 25 to 55 and the total acid between 82 and 105. Cases were also referred to by Hecker, Raudnitz, Bauer and Deutsch.

As far as I know, however, there is no study in the literature of a series of gastric examinations in supposed hyperchlorhydria in children. In the cases I am reporting, seen in private practice, gastric examinations were made, gastric juice being obtained one hour after a test meal consisting of a few biscuits and a glass of water. The analyses were made by a modification of the Töpfer procedure. They showed hyperacidity.

The constitutional symptoms of the children in this group were interesting. They were nearly all dark or sallow complexioned. They tended to be hyperactive and yet tired easily, especially in the afternoon. They were all of the nervous type. In view of the observations of John Rogers on fatigue disease in relation to the thyroid and adrenal glands, and their effects upon the gastric secretions and hyperchlorhydria, determinations of the blood pressure were made in those above the age of three. It was found consistently lowered. Blood sugar determinations were also made. Results are shown in the following table:

	Free HCl	Total HCl	Blood pressure	Blood sugar
M. B.....	58	70	0.85
I. G.....	62	80	70-55	0.72
E. H.....	60	76	80-64	0.80
J. L.....	60	78	75-60	0.78
J. L.....	48	85	70-58	0.72
L. M.....	48	90	78-60	0.90
A. H.....	38	70	68-60	0.65
B. S.....	40	60	0.95
J. K.....	50	84	80-60	0.75
P. S.....	40	60	75-60	0.88
J. B.....	42	76	70-55	0.80

The abdominal pain was variable, sometimes occurring directly after meals, sometimes in the morning or at night, or awakening the child from sleep. It was nearly always umbilical or epigastric. It might last for hours. The anorexia was also variable, being intermittent in some cases, in others constant, and in a few characterized by being pres-

ent between meals, but destroyed by a small amount of food. The vomiting occurred most frequently after meals, especially after the evening meal.

CASE I.—M. B., two and a half years old. Patient suffered from abdominal pain, with frequent vomiting after meals, and occasional attacks of pain at night. Physical examination of the abdomen was negative. The child's breakfast consisted of orange juice at 7.30 and at 8.30 cereal, against which she rebelled. At 12.30 she had lunch, with hot broth or soup as the first course, and at supper she ate an egg. Test meal showed hydrochloric acid 58, total acid 70 and blood sugar .85 per cent.

CASE II.—I. G., aged five years. Patient had a poor appetite and presented alarming symptoms of fatigue in the afternoon. Breakfast began with orange juice and the patient ate a good deal of ice cream and pastry with candy and milk frequently between meals. Physical examination of the abdomen was negative. Test meal showed free hydrochloric acid 62, total hydrochloric acid 80, blood sugar .72 per cent. and blood pressure 70-55.

CASE III.—E. H., aged four years. Patient suffered from frequent paroxysmal attacks of abdominal pain. Several attacks of pain occurred at night, with screaming, hypodermic injections of morphine being required to quiet the child. Physical examination of the abdomen was negative. Orange juice was given in the morning before breakfast and highly seasoned beef or a chop, with other condiments, for lunch. Test meal showed free hydrochloric acid 60, total acid 76, blood sugar .80 per cent. and blood pressure 80-64.

CASE IV.—J. L., aged six years. Patient suffered from lack of appetite, with nausea before meals, and occasional attacks of vomiting and abdominal pain. Sliced orange or other raw fruit was eaten for breakfast and salad with French dressing for lunch; coffee at night. Physical examination of abdomen was negative. Test meal showed free hydrochloric acid 60, total acid 78, blood sugar .78 per cent. and blood pressure 75-60.

CASE V.—J. L., aged four years. Patient suffered from abdominal pain and indigestion and was always thin. There was a history of difficulty in feeding in infancy and various attempts to fatten. The child was ten pounds underweight and was being fed every two hours, with ice cream at least once a day and six teaspoonfuls of cane sugar with cereal. Physical examination of abdomen was negative. Test meal showed free hydrochloric acid 48, total acid 85, blood sugar .72 per cent. and blood pressure 70-58.

CASE VI.—L. M., aged five years. The patient was thin and suffered from recurring abdominal pain and frequent colds. Epigastric pains occurring paroxysmally after meals, sometimes spreading to appendiceal region, were relieved by bicarbonate of soda. Physical examination of the abdomen was negative and fluoroscopy showed hyperperistalsis of the stomach. Test meal showed free hydrochloric acid 48, total acid 90, blood sugar .90 per cent. and blood pressure 78-60.

CASE VII.—A. H., three and a half years old. There was lack of appetite, with abdominal pain

occasionally. The child's appetite was so poor that it would touch no food except milk, of which it took about a quart and a half a day at irregular intervals. He vomited often small quantities of sour smelling material. The child was dark complexioned, pale, flabby and underweight. Physical examination of the abdomen was negative. Test meal showed free hydrochloric acid 38, total acid 70, blood sugar .65 per cent. and blood pressure 68-60.

CASE VIII.—B. S., aged two years. The child suffered frequently from abdominal pain and anorexia. Breakfast consisted of orange juice with a fried or a scrambled egg; lunch, steak of roast meat with hot soup; supper, boxed cereal and ice cream or candy. Test meal showed free hydrochloric acid 40, total acid 60 and blood sugar .95 per cent.

CASE IX.—J. K., aged four and a half years. Patient suffered from vomiting after meals. Appetite was not very good but patient ate his meals and vomited after nearly every meal. The vomitus was very sour. The vomiting, which occurred about an hour after every meal, was occasionally preceded or accompanied by umbilical pain. The child was pale, underweight, and generally constipated. Physical examination of the abdomen was negative. Test meal showed free hydrochloric acid 50, total acid 84, blood sugar .75 per cent. and blood pressure 80-65.

CASE X.—P. S., aged four years. The patient was sallow, poorly nourished, had a poor appetite and suffered from eructation of gas and abdominal cramps after meals. The abdomen was negative except for tenderness in appendiceal region. Test meal showed free hydrochloric acid 40, total acid 60, blood sugar .88 per cent. and blood pressure 75-60.

CASE XI.—J. B., aged three years. Patient suffered from frequent umbilical pain, sometimes related to meals, and cramps which at times were very distressing. The appetite was capricious and there was occasional vomiting. Physical examination of abdomen was negative. Test meal showed free hydrochloric acid 42, total acid 76, blood sugar .80 per cent. and blood pressure 70-55.

Of these eleven children ten were given orange juice in the morning, when the stomach was relatively empty. All of them received in addition other gastric irritants in the form of highly seasoned or sugar concentrated foods. That these played a part in the production of the symptoms was demonstrated by the therapeutic response to their elimination. The return to orange juice, regarded quite superstitiously by some mothers as a divinely ordained constituent of the diet, as well as an appetizer, always produced a return of the symptoms. Yet many children do take orange juice and other fruits, as well as the other gastric irritants, and are apparently not adversely affected by them, no interference with their appetite nor vomiting or abdominal pain being produced.

The occurrence of these symptoms may perhaps be explained by the fact that they occur in a certain type of child, generally dark complexioned, with a tendency to low blood pressures and low

blood sugar and a relatively abnormal fatigability. This type seems to be disposed to a development of hyperchlorhydria under irritant food provocation. This predisposition perhaps depends upon a certain relation to the adrenal-sympathetic-thyroid mechanism of the organism, which controls the nerves conducting, inhibiting or stimulating impulses to the gastric cells. Although this remains to be determined, these cases point to the existence of a constitutional type, perhaps dependent upon a constitutional hypoadrenalism, in which gastric irritation and bad hygiene produce hyperchlorhydria, hyperperistalsis or disturbances of peristalsis of the stomach and accompanying symptoms.

All of these patients have done well under a general hygiene régime, with removal of the gastric irritants from the diet. Antacids and adrenal nucleoprotein also seemed to assist in the restoration of conditions to the point at which the symptoms disappeared, and general wellbeing returned.

The Prevention of Measles*

By ISAAC W. BREWER, M. D.,
Watertown, N. Y.

The importance of measles as a cause of sickness and death is not appreciated. In many cases the patients are never seen by a physician and of those who do come to the attention of a physician most of them are seen but once. For a number of years I have been deeply interested in the prevention of this disease and think that probably my experience may help others to avoid the errors into which I have fallen.

In the following table are presented some brief data regarding the morbidity and mortality of this disease which show its importance:

COMMUNICABLE DISEASES IN THE UNITED STATES AS REPORTED TO THE UNITED STATES PUBLIC HEALTH SERVICE.

Average for the years 1913 to 1919.

Disease	No. of cases	Case rate in 1000 of population	Death rate in 1000 of population
Measles	404,548	5.2	0.11
Diphtheria	110,992	1.3	0.16
Scarlet fever	100,321	1.2	0.03
Typhoid fever	59,103	0.7	0.12
Smallpox	37,085	0.4	0.005
Cerebrospinal meningitis	21,998	0.04	0.04

As a cause of sickness measles ranks first and as a cause of death it is third among communicable diseases. However, we know that most of the deaths from diphtheria are unnecessary and that typhoid fever can easily be prevented. In the case of measles it is quite probable that there are many deaths in which this disease is an important contributory cause. Vaughan, basing his opinion on the statistics of the Army during the World War, says: "Where one man without measles has pneumonia, two or three (2.6) men with measles have pneu-

monia. . . . Thus in 2,075 cases of pneumonia following measles 888 or 42.7 per cent. of the patients died. In 8,432 pneumonia cases not following measles 949 patients, or only 11.3 per cent., died. Measles thus not only predisposes to pneumonia, it predisposes to fatal pneumonia."

If there is ever produced a measles vaccine as potent as the typhoid vaccine, measles will disappear from the medical nomenclature, provided the people will avail themselves of this vaccine, which is rather doubtful. Until such a vaccine is developed and used we shall have to depend upon isolation to prevent epidemics of measles.

We all know that during the preeruptive stage the disease is highly infective and that with the appearance of the eruption the potency of the virus seems to diminish. It is only in rare instances that we are able to place a patient in isolation during the pre-eruptive stage, and that when the case comes to our attention the damage has to a large extent been done. In other words, the isolation we impose is of secondary importance. Unless we can arrange to have all cases isolated during the catarrhal stage we shall have epidemics of measles at regular intervals as soon as a nonimmune population of sufficient size grows up in the community.

In Watertown we have an epidemic about every third year and just now we are in the midst of one of the most extensive of which we have record. It began in January and there was an interval of eleven days between the primary case and the secondary ones arising from it. At that time we endeavored to discover the cases before the patients came down with a cold, and in a number of instances the Koplik spots were found before there were other symptoms, but many cases were not de-

*Read at the Conference of Sanitary Officers, Watertown, N. Y., May 25, 1921.

tected. In one instance a child was found in school with a rash on the body. The mother remarked that she was not sure it was a case of measles and therefore sent the child to school. We kept up our inspections until it was manifest that nothing further could be accomplished by that measure. So our epidemic got started and is now burning itself out and will cease when all the nonimmunes have been attacked.

In contrast to this are the conditions which obtained at a military station during the first nine months of the World War. Our post was designated as a reorganization camp and early in April, 1917, recruits began to arrive. With the first detachment came a man who was sick with measles in the eruptive stage. He was at once isolated and all of his companions who had not had the disease were inspected daily, their temperature being taken in the afternoon. Those with an elevation of temperature were isolated, and in this way we found a number of cases before they reached the catarrhal stage. Although there were constantly importations of the disease it did not spread beyond the primary contacts in any instance. It may be said that the disease was not virulent, but in a regiment which was camped nearby, and for a long time was not under our jurisdiction, they had numerous cases of measles during that time. Later when I became sanitary inspector for the entire camp and the same measures were put in effect there was no further spread among the new men.

This last story was told at the 1917 meeting of the American Public Health Association and was re-

ceived with doubt. Many of the best men in the country seemed to feel that it was impossible to prevent an epidemic of measles. Without doubt it would be difficult to inaugurate the plan followed at the camp but I know of one place where it was carried out with success. I do not believe in doing nothing and as soon as this epidemic has passed I propose to lay plans for combating the epidemic which may be expected in 1924.

We must acknowledge that the so-called cold is the point of attack and I hope so to impress this community that before the next measles epidemic they will see that all children with colds are isolated, or at least excluded from school. I have been told that the public would never stand for it, but I believe they will as soon as they realize what it means.

The trouble with most of our health legislation is that it comes before there is a demand for it. Not understanding, people resent the restrictions it imposes, and in many instances it is impossible to enforce the laws. We have a shining example of this in the regulation against spitting. In very few cities is it enforced, in most instances because the judges or the jury do not realize the importance of the ordinance.

In addition and to support the campaign of education which it is proposed to inaugurate, I hope our sanitary laws may be so changed that there will be less restriction of the liberty of the other members of the family. I think the time has come when we must recognize that in most of the common diseases it is not things but persons who are dangerous.

Children's Fears

By FRANCES RUSS-BARKER,
London,

Children's Era Organizer for Infant Welfare under the Auspices of National Baby Week Council.

Scientific investigators, doctors, and those who have studied child life, tell us that the making or marring of the child's bodily health, and, as a result, of its character and career, is very largely accomplished in the first years of its life, when the emotions of fear and love begin to develop. Perhaps the first to develop is fear; it is on record that an infant twenty-three days old has been known to evince fear. Clever, high strung children have, as a rule, many fears, most of them creations of their own little minds, but these same fantastic fears very often grip the child with such intensity that the effects on its life and health are sometimes of a most detrimental and lasting character.

Dr. Leonard G. Guthrie says: "The importance, long neglected, of acquiring knowledge of children, as well as of their diseases, is now recognized. If children were ill or ailing, the doctor was called in to prescribe for disease, but not on their management; he was not asked to see a child because it was wayward, but because it was wasting; not because it was dainty, capricious in appetite, refusing

food considered good for it and craving for all food that was unwholesome, but because it had pains in the stomach. Advice was not asked for peevish, passionate children, nor for those who were afraid of the dark or unnaturally timid, absentminded, or brooding and morose, jealous, spiteful, or cruel, nor for mischievous, untruthful, dishonest, or immoral children" (1).

All such defects were regarded as moral rather than morbid, and were treated as such. It was long before it was recognized that a child might be dull and stupid in consequence of defects of sight and hearing. We are likely to attribute an enormous variety of symptoms to one cause in particular, instead of to many different factors, and when we have removed or treated the presumed cause, we are much concerned because the child is not materially better. For instance, a child has night terrors, and as indigestion will certainly give rise to bad dreams, we think to stop the night terrors by treating the child for dyspepsia. Or headache is the complaint, and having observed a slight error in

refraction, we are disappointed that the headaches do not disappear when suitable glasses have been obtained.

In the case of adults, the effect of mental troubles on the course and origin of illness is well recognized. Medical treatment alone will not cure insomnia in a clerk who has been robbing a till, or dyspepsia in a wife who is jealous. Yet where children are concerned we often forget that the influence of their mental troubles may be as great or greater than our own in causing and prolonging their complaints. We know that excessive emotion of any kind, whether restrained or unrestrained, produces lowered vitality and prostration, enfeebled circulation, and disorders of the whole system; hence the importance of recognizing the presence of emotional excitability in early childhood.

Those who are neurotic will sympathize with the statement of George Eliot that emotional sufferings in early childhood are very great indeed: "that they were intensified by being neglected or ignored; that they affected our health as much as our happiness, and that we bear their traces still."

Dr. Guthrie traces ill health in after life, in many men and women of the greatest genius in our country, "to want of sympathetic and judicious treatment in their youth. Parents being nowadays fully alive to the effect of mind upon disease, expect to be told how ill health may be averted by mental as much as by medical treatment."

All children have an inborn sense of justice, and a corresponding inborn resentment of injustice, hence the importance of sifting evidence whenever an opinion is to be pronounced for or against the child. It is within the knowledge of the writer that a child spent many sleepless nights because of a wrongful accusation. No child should ever be allowed to go to bed brooding upon its wrongs, supposed or otherwise. This is likely to engender smouldering resentment, jealousy, or even hatred, and to darken the child's outlook on life, thereby having lasting ill effects upon its health.

Referring again to fear: Children, as a rule, have such fine susceptibilities that they read accurately the feelings expressed in the faces of those about them, and gauge exactly the emotional atmosphere around them. If mother comes downstairs not feeling good humored, the sensitive child feels it and his own mental attitude is similarly affected. If mother is nervous or unhappy, her emotions react upon the household; hence the importance of a mother learning to control her own emotions, expressions, and tone of voice, that in turn she may teach her child proportion and control. Take an everyday instance: Tommy, running along, falls; he has perhaps slightly grazed his knee, but being interested in his play would have recovered his balance and gone along as before. Mother rushes up, consternation and fear written on her face. "Poor Tommy," she exclaims, "where is my darling hurt?" etc. Tommy looks at the dirt on his clothes, sees a faint scratch on his knee, glances at mother's telltale face, and goes off into loud howls, showing at once the effect of her mind on his.

There are other objects of fear: Fear of the doctor, the policeman, the dark, witches, giants, hob-

goblins, dogs, the sweep, fear of being alone; all these and many other fears, if not sympathetically treated, wear down the child's nervous system, lower his vitality, render him susceptible to a thousand and one ailments, and in many cases account for morbid conditions in after life, from mental trouble downwards. To meet a child's fears with harshness or ridicule is a criminal fault, and is equal to mentally and morally murdering him. Children's fears should be met with sympathy and kindness, and, above all, with explanation.

The development of love in the very young child is fostered chiefly by example. Everyday kindness, gentleness, loving ways, etc., should surround him in the home and also in the school. In the home where there are jars, angry words, nagging, ungracious or rough behavior, we find that the children imitate their parents' methods of speech and conduct, and there is little atmosphere in a home like this for the development of the love inborn in every heart. In my experience the remark is constantly heard, "I can't understand why my girls and boys will not stay at home." The answer is, if the attraction of love and cheerfulness and sociable conditions are not in the home, those necessities will, of course, be sought elsewhere. Love should be developed in the home together with the idea of service. Children should be taught to do little acts of service from earliest infancy for mother, for father, and, above all, for each other; boys taking equal share with girls in home duties and service. Judicious praise should always be bestowed for such acts of kindness and service, because this will stimulate in the child a desire to become more worthy of the parents' loving appreciation. Parents and teachers should realize that loving ways and an appreciation of the child's efforts will bring forth results undreamed of, acting as a tonic, physical and mental. Nagging and faultfinding prey upon the nerves, mind, and general health, and make children resentful and stubborn. As a woman once said to me: "The children are so naughty, I'm always at 'em." What a hopeless situation for this family!

The old adage, "Know thyself," points out the only means by which it is possible to acquire knowledge of others. Therefore, the study of this fascinating and all important subject of psychology (which means selfknowledge) is recommended to all who have the interests of the young at heart.

But even knowledge will not suffice, unless its application is enforced with sympathy. The power to feel with a nervous child, to realize the burning sense of injustice in the heart of a child wrongfully punished, to look at life through a child's eyes, this power will do much to make the way smooth for both parents and children, both teacher and taught. Tact has been described as educated love, and sympathy might be described as love that takes trouble. It is much easier to scold a nervous child than to try earnestly to enter into its fears, and so banish them; but it is not too much to say that, for many a child, the treatment it receives in these respects is a matter of life and death.

A Suggested Form of Treatment for Mental Deficiency in Children

By J. A. MILLER, M. D.,
New York,

Neuropsychiatrist to the Educational Clinic, College of the City of New York.

More than a decade has passed since the innovation of treating all types and grades of mental retardation in children and young adults by means of glandular therapy. And for this period various results from this method of treatment have been published all more or less optimistic as to the future progress on these lines. Following this theory the tendencies of the times have been an attempt to increase mental capacities by stimulating the brain cells or bringing into activity dormant brain cells through these glandular extracts by some obscure action.

It is my belief that this method of treatment is due to the improper understanding of the condition and causes of mental retardation and mental defectiveness. We cannot stimulate a dead body or an absent one. For example, a weakened muscle can be made strong by suitable treatment and so increase its activities, but medical science, thus far, has not discovered any method whereby dead or absent muscle tissue can be brought to life and made to function in a normal way. So let us start with the assumption that each human being is endowed with a certain fixed amount of acting brain tissue. This gives each individual a definite measurable quantity of mentality that cannot be increased. This mentality, however, can be left idle or can be decreased by disease or accident during the period of life.

From these statements the following conclusions must be drawn: The child at birth has the same amount of living active brain cells as it will have when grown to adult age. During the time intervening from birth to adolescence these brain cells are stimulated and exercised until they function at their greatest power. The intelligent child at six will not be the dullard at sixteen, barring disease or accident that may cause definite or obscure organic lesions. The dullard at six will be the dullard at sixteen come what way. Bearing this in mind let us for the present, until medical science shows more specific methods, treat these various mental retardations and defections by means that will bring the best results for the individual and the general public. The problem now for consideration is the best form or method of treatment for the retarded or the defective child.

At what age can we detect any subnormality of mentality of any considerable degree? Usually unless the retardation is extreme the knowledge is unfortunately concealed unwittingly until the child goes to school. And even then, because of our present day methods, if the child is of a pleasant disposition and not marked by any of the stigmata of degeneracy it may escape notice until considerably older. Or in the higher strata of society where private tutoring is substituted for school the knowledge of the child's inferiority may not be known

until adolescence. Therefore, I suggest that all children should be examined and their mental capacity ascertained at the age of about five or six for in the treatment of the retarded or defective child the earlier started the better.

In contrast to the good that can be done we must consider what will become of the children of low mentality if the proper steps are not taken immediately for treatment and care. Offhand, I dare say a great many of these children will be public, social or moral menaces. The majority will help keep up the number of inmates in the prison, the poorhouse, and other public and charitable institutions. They will propagate species of as low or lower mentality, potential criminals, aments and dements.

We know that there is a definite curve of distribution in mental capacities, as has been shown by

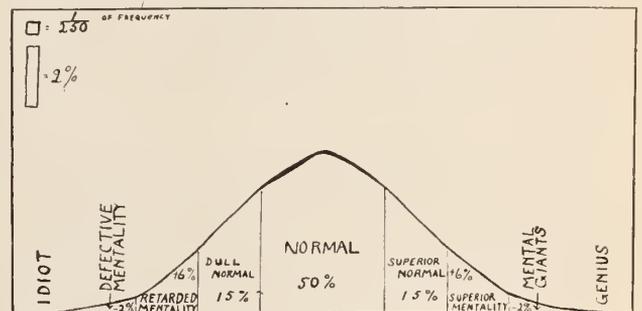

FIG. —Chart showing approximate frequency of various degrees of mentality.

the extensive examinations made by army psychologists and educators, the highest and greatest portion of the curve representing the average normal human being with regard to mentality. This curve descends gradually from either side of the highest point to the genius on one side and the idiot on the other.

The accompanying diagram shows as near as possible the true relationship of the various degrees of mentality to each other and the approximate frequency. The midsection of the curve represents the normal group with the dull normals on one side and the superior normals on the other. The next right side section represents the superior mentality and then the mental giants running to genius. Correspondingly on the left of the dull normals we have the group of retarded mentality and then the defective mentality running down to the idiot.

Having been unsuccessful in our attempts to treat the individuals falling in the lowest two groups (almost ten per cent. of the children) by means of glandular therapy, under the assumption that they were suffering from some disturbance of their endocrine system, let us devote our time and expend our energies in believing for the present that these individuals are normal mentally as one

of that specific group. To illustrate my meaning, let us suppose that a ten year old child has a mental age of seven years. We would then call that child a normal seven-ten child or in terms of intelligent quotients a normal of 70 I. Q. child, all other things being equal. This in spite of the fact that medically we have heretofore termed the child mentally defective or feeble-minded or retarded or whatever term might have been used by the diagnosing physician before starting on a more or less lengthy attempt to cure or improve by means of the glandular extracts, only to be disappointed except in cases of cretinism. Now should this child be a social defect then we would term the child a seven-ten social defect or a 70 I. Q. social defect. And again a physical defect, glandular defect (cretin), or neurotic, moral or any other defect as the case may be.

This tells us the true defect and the treatment can be given in accordance. In other words it is more important to treat the defect whenever present and not the mentality which may be normal for that individual. The aim of the treatment would then be to make the children able to care for themselves totally or in part in after years.

To do this these children must be examined thoroughly both medically and psychologically at an early age and at periods varying from six months to a year. All their physical, social, neurotic and other defects must be noticed and the future treatment be governed by the findings. Their temperament and physical possibilities must be studied for ultimate use.

With the knowledge thus gained and knowing that all these children have a definite capacity for learning, steps can then be taken to lessen their great handicap by means of training in suitable schools or institutions and the utmost done to educate them to the fullest of this capacity, bringing out any latent or potential powers or individual asset, all methods bearing on the one theory of making these children self-supporting in whole or in part in adult life.

The best asset is a sound body and too much stress cannot be placed on the importance of maintaining the good physical qualities that a child has or improving the condition of those not so normally endowed. Variability of mentality is great, as shown by the diagram, but the variability in manual ability is small, therefore attention must be paid to the physical possibilities in order to make up for the handicap of a low mentality.

Not being an educator I will suggest only in a general way the proper methods to school and train these children. First of all there must be special or individual schools for these children so that they themselves may not be imbued with the idea that they are abnormal in some unknown way, as is so often the case among these children who attend schools of the modern system. Special schools should be provided for the training and education of these children who are not up to par mentally, compared with the average child. These mentally subnormal children should be graded both according to mentality and to age. A fifteen year old boy will find no incentive in working alongside of an eleven year old boy, even though they have the same mental capacity. Special subdivisions or departments should be made in the various grades to train or treat any defects that may be found existing in individual cases, such as physical, social, moral, or other defects.

The training and treatment should go to the home by means of social workers wherever needed, and where the home is not conducive to proper training or treatment, due to parental indifference or antagonism, the child should be cared for in an institution.

If these suggestions are followed out and too much of the child's time is not wasted by attempting to bring about a cure or even a betterment by means of glandular therapy in the child's pliable years, much will be accomplished and a far greater percentage of these children of low mentality will be able to become entirely or partially self-supporting.

Chronic Effects of War Gassing

Notes on the Examination of 1200 Cases

By Z. I. SABSHIN, M.D.,
New York.

The lethal gases have played an important rôle in the recent European war. From the military viewpoint it proved to be an efficacious agent, throwing thousands out from the line of active duty, and, while on one hand it might have made the impression of being comparatively humane, it has nevertheless proved to be the cause of many of the disabilities of the American expeditionary force. From my own experience in handling exservice men who applied to the government for compensation, although with no definite statistical data, I may state that about thirty-five per cent. of all the disabilities are traced back to the gassing, with or without other injuries. In taking the histories of these patients I

learned that many of them were not directly gassed in the front lines, but were affected by handling the clothing and other articles of those who were gassed, or by contact with munitions that were in the vicinity of the gassing.

The immediate and early symptoms of gas poisoning are well known to those who were overseas. Although the chemical composition of the gases varied, some of them affecting mostly the lung tissue (phosgen), while others affected every tissue with which they came into contact (mustard), the usual case, however, was a picture of an inflammatory reaction of some part, or the entire respiratory tract. It seems that all the gases are respiratory

irritants, and, judging from the physical findings later on, they have also had an escharotic action upon the lungs. The chronic effects, however, are not confined to the respiratory tract only. We find that every system of the body, as well as the special senses, were disturbed, though some may be considered as complications. The usual complaints given by the patients, whom I have seen from a few months to two years after having been gassed, were as follows: cough, pain in chest, dyspnea, fatigue, dizziness, palpitation, vomiting, indigestion, impaired vision, headaches, aphonia, and nervousness. The first important fact noted from the examination and reexamination of these patients is that the gassing was either a mild one, or of a severe nature. On the one hand, I found marked bronchial disorders a few months after the exposure to the gas, and have seen these same cases fully cleared up several months thereafter. On the other hand, I noted the persistence of the abnormal subjective and objective findings, even over two years after the gassing. The pathology of this latter group of cases is not very clear, and one is likely to change his opinion on examination and reexamination of these patients.

The first phenomenon that attracted my attention was the occurrence of chronic pulmonary tuberculosis in these patients, and I have wondered as to what may be the relation of war gas to pulmonary tuberculosis. I have asked this question of one of the older men in the army service, and his answer was that the tubercle bacillus was killed by the gas, and hence gassing did not cause tuberculosis. I could not contradict this statement, and was puzzled, as my list of chronic pulmonary tuberculosis in the gassed exsoldiers was growing larger. The next group of cases with a peculiar morbid anatomy from the causative point of view is the one with typical subjective as well as physical findings of bronchial asthma. I do not know to which of the existing theories as to the cause of asthma gas poisoning can be added. The fact remains that the war gassing did cause bronchial asthma. Not less interesting, and at first more mysterious, is the group of cases with chronic cardiac disorders. Here are cases with all signs and symptoms of a valvular lesion, regurgitation, stenosis, or both, with no history of rheumatism or any other known cause of heart disease, and the trouble starting from the day of the gassing. There are other cases with tachycardia as the only finding, some of which resemble greatly a clinical picture of hyperthyroidism, and may be easily mistaken as such in private practice.

I have mentioned these groups of cases because of the puzzling relation of the cause to the pathological sequelæ. The bulk of my cases, however, were recorded as chronic bronchitis. In some we have added the term emphysematous type, in others asthmatic type, disregarding the terms mild or severe, which were often used. All these cases came in with the chief complaint of cough and shortness of breath. The physical findings were the usual signs of a bronchitis. The peculiar feature is the marked roughness of the breath sounds, mostly found in the interscapular region. In some cases this type of bronchial breathing resembles actual sawing of wood, while percussion would give nearly

normal findings, with or without other auscultatory abnormalities.

The etiology accounting for the form and progress of all the chronic disorders mentioned above is only a matter of speculation. The first thing the gas does is to irritate the lung tissue, thereby causing an inflammation. Associated with that there may also be deep-seated necrosis of the parenchyma, which later probably heals by fibrosis, thus accounting for the roughened respiration. The inflammatory process in some cases is accompanied by the development of fluid in the alveoli, and violent coughing, caused by the irritation, results in the destruction of the alveolar epithelium and bursting of the air vesicles, thus developing a disruptive emphysema. With the edema and congestion of the lungs there is also probably some thrombosis, slowing up the pulmonary circulation, causing an oxygen deficiency in various systems and organs, and in turn, sooner or later, leads to a disturbance in the right heart. There may also be some changes in the concentration of the blood, which, together with the lack of oxygenation, causes changes in the cardioaugmentory and cardioinhibitory centres, thus accounting for the cardiocirculatory disorders. The gas most probably is absorbed through the lungs into the system and causes the general symptoms. Destruction of the lining of the respiratory tract predisposes to invasion of the lungs by bacteria from the mouth, so that a tuberculous process can be easily started. The lowered resistance is also demonstrated by the fact that influenza occurred about twice as often in the gassed soldiers, as compared with those who were not gassed. Contrary to what one might expect, it seems that the negro had a greater resistance to the gas, as seen from the comparatively milder symptoms in this class of patients.

As stated above, the bulk of my cases were those of chronic bronchitis. It may, however, be of some interest to copy some of the figures from my record, which I do not consider of any statistical value. I have had 104 cases of chronic pulmonary tuberculosis, fifty-four with bronchial asthma, forty-eight with chronic valvular disease of the heart, thirty cases of tachycardia, twenty-two cases of chronic myocarditis, twelve cases of chronic nephritis, six of neurocirculatory asthenia, and eight cases of chronic gastritis with or without dysentery. The special senses in my cases were affected as follows: Sixty-eight had chronic conjunctivitis, four had retinitis, twelve had chronic otitis media, twenty-three cases of chronic laryngitis. Eighteen were diagnosed as suffering from neurasthenia. From the histories I also learned that fourteen were blind from one to four weeks after their having been gassed, one had loss of speech for five months, one still has loss of smell, and two have lost the power of erection.

The practical question which faces the community as well as the government is the extent of permanent injury and the period of disability of the gassed soldiers. From this point of view this question proves to be much more complicated than it was originally believed.

1393 FRANKLIN STREET.

Editorial Articles

DIPHTHERIA

Professor Schick's article on the Predisposing Factor in Diphtheria, which appears on page 197 of this issue, commands special attention, both an account of the eminence of its author and the importance of the subject. The very greatness of the accomplishment reminds us forcibly how much remains to be done before we can interpret with any degree of certainty even those phenomena of infection which are easily observed and of common occurrence. The author refers to the early struggles of the young science of bacteriology against the ever alert powers of darkness. This remark serves as a useful reminder of the fact that many of our basic truths were only yesterday held to be fantastic heresy. We need only refer to the fight that centred around the present conception of immunity and the phenomenon of bacterial carriers.

Diphtheria has lost much of its element of dreaded terror since the advent of specific serum therapy. It is well to remember, however, that the disease is not as harmless yet as many observers who do not come into close contact with it may be led to believe. It is left to pediatricists and the hospital staffs to realize to its full extent the peculiarly treacherous character of the affection.

The case incidence of diphtheria in New York city reached its recent climax of 433 cases in the week of April 30th. This was by far the highest figure shown by any individual disease during that period. On July 23rd the incidence had dropped to 136, while the mortality amounted to nine cases during the week, which represents one per cent. of all deaths. Though the death rate of laryngeal infection is no longer ninety per cent., we still find the worst features of diphtheria in this variety. Holt estimates the mortality of laryngeal diphtheria at forty per cent., while many English observers place it even at fifty per cent. and over. If we conclude this short survey with a reference to cardiac and nervous sequelæ, we will have succeeded in emphasizing the undiminished urgency of combating diphtheria.

In his present paper Professor Schick gives us an interesting outline of the early history and later development of the intracutaneous test. He also indicates the gist of the theoretical considerations and some of the experimental work which form its scientific basis. In discussing natural protection against infection emphasis is laid on the mechanical factor, while no special reference is made

to the defensive forces centred in the vital processes of cell function. One may wonder if a more active share in the defense of the body should not be attributed to the cells of the pharyngeal mucous membrane, rather than to the mechanical structure of the tissues. The author mentions an instance, where trauma broke down the efficiency of the mucosa and an attack of diphtheria resulted in a carrier after a tonsillectomy had been carried out. Is not the process identical in the type frequently met with in clinical practice, where an acute non-specific tonsillitis is followed after an interval by an attack of true diphtheria? We need only presume that the onslaught of the first variety of organisms, the shock troops, damaged the previously healthy epithelium in such a way that the originally powerless diphtheria bacilli found a suitable soil in the now devitalized tissues. MacCallum's *Textbook of Pathology* contains an interesting photomicrograph showing an advanced line of streptococci actually within the tissues of the pharynx, while diphtheria bacilli have gained a footing on the more superficial necrotic portions. Though other explanations cannot be altogether ruled out, it may be admitted that it has all the appearance of a case of genuine symbiosis. In any case, the fact that the mucosa becomes damaged in the course of diphtheria, makes it highly probable that absorption of toxins of other than diphtheritic origin does actually take place. This is a possibility which seems to us worthy of more consideration than has hitherto been accorded to it.

Schick has forged a weapon which enables us to attack diphtheria from many different points of vantage. For the first time we are able to determine the susceptibility of large bodies of individuals with speed and accuracy and within the bounds of economic possibilities. It is, perhaps, with justifiable pride that we point to the progressive spirit our health department has shown in quickly appreciating the potentialities of the test and in utilizing it on such a large scale without courageous enterprise. The good results obtained in New York city are due to a great extent to the wise publicity service which has widely diffused a knowledge of the merits of the test. We remember with admiration the public spirited demonstration given at the recent New York State Medical Society exhibition in Brooklyn.

Schick's test has confirmed the findings of clinical observation with regard to the dangerous age. Children between the ages of six months and six years

show the greatest susceptibility. The author points out that in at least one important point the test is superior to bacteriological examination: this is the decision, whether a carrier of diphtheria bacilli in whom tonsillitis develops, suffers from a superimposed acute attack of diphtheria, or whether he continues to be resistant to the specific organism and merely has a septic sore throat. In the latter case, the bacteriological examination would indeed show the presence of Klebs-Loeffler bacilli, but Schick's test would be negative and thus reveal the true state of affairs. Again, during an epidemic of diphtheria in an institution, such as a school or a hospital, there would be no need to inflict the annoyance inseparable from a course of serum immunization, on those individuals who are naturally protected, as demonstrated by the Schick test. Finally, we may point out that the test has been and to an even larger extent in the future will be an important help for researches into the nature of immunity and infection. The test has added another triumph to the fair fame of Æsculapius's youngest daughter, Prophylaxis. It also is endowed with a special attraction, inasmuch as it stimulates the development and rewards the public spirited application of a rare and precious faculty of the mind of man—foresight.

PEDIATRICS AND OTHER THINGS.

This issue of the *NEW YORK MEDICAL JOURNAL*, as well as that of August 3d, is devoted to papers on the subject of pediatrics. Many of them will be found useful and most of them present new findings or shed more light on things known but not always emphasized.

The mental and nervous factors are among the most important considerations in the study of child life. The conditionings of the first few years of childhood, as shown by the studies of Freud, Hug Helmuth, White, and other workers are the most important in the entire life cycle of the individual. We have always attempted to be fair and publish papers by men of standing even though we did not agree with them. In this instance, we publish a reactionary paper by Dr. Charles W. Burr, of Philadelphia. He has either ignored or failed to keep up with the literature on the subject. It would be well if he would get in touch with the works of Jones of England, Hug Helmuth of Germany, and Kempf and White of America. He would then secure a better understanding of the causative factors in the behavior of children. The great difficulty with Dr. Burr is that he only observes things on the surface and never gets down to fundamentals. He classifies children into groups. He for-

gets that they are individuals with a personality in the making. He accepts them as they are and attempts to label them. It is depressing to find workers holding positions of prominence clinging to dogmas long since relegated to limbo, calling the brain "the great organ of thought and feeling" when we thought that this scholastic point of view had been abandoned even before James and Lang had put forth their theories. The author frequently naively seeks answers for questions which are no longer mysteries except to those who refuse to see: ". . . whereby new potentialities whether for evil or for good arise, we do not know." It would be more accurate if the personal I were substituted for the more amorphous editorial we, for there are workers in this important field who do know, and who base their therapy upon their knowledge. We would not attempt to say that psychoanalysis would have improved the products of Dickens, but we do feel that a better understanding of human behavior would materially improve Dr. Burr's concepts of the nervous child. His therapy consists of repression, repression of the things that should be brought to light and examined and then synthesized, but it is difficult to do this when the physician himself is groping about and has lost contact with reality. Dr. Burr's paper, however, is not wholly bad. One statement in particular is extremely well put—"We must relearn that innocence, which after all is ignorance, though pretty in a baby, is hideous in an adult; that hiding nasty truths does not make them untrue or abolish them and that work is the one thing worth while." This is sound common sense, and it does not seem to be in keeping with most of the reactionary parts of the paper.

VACCINATION METHODS

The average physician regards vaccination as more or less of a nuisance—an unimportant task to be relegated to the office nurse or to be hurriedly performed by the doctor himself with a prayer that a bad arm may not follow. As a rule, the patient's family does the afterdressings according to their several lights, and if the vaccinee goes to school a certificate of vaccination is issued if any sort of a scar results. There is no generally followed vaccination technic, some scratch, some bore, and some squirt the vaccine beneath the skin with a hypodermic syringe. There is no universal site for vaccination; the deltoid insertion, right or left, the inner aspect of the arm, the calf and the thigh being used alike. There is no definite rule regarding revaccination; no uniform method of diagnosing a "take," an immune reaction, or a failure. In other words, by

and large the practicing physician is neglecting a tremendously important public health duty.

This results, perhaps, from the fact that the average practitioner sees few cases of smallpox, and those which come to his attention are generally benign. Hence, unconsciously, smallpox has come to be regarded as an almost negligible danger. Yet mild smallpox is pretty generally distributed throughout the United States and if physicians continue their present vaccination technic we are likely to see a good many old fashioned virulent cases. Certainly, improperly performed vaccinations do not help the cause of vaccination; one bad arm in a community will undo a year spent in carefully teaching public health, and furnish the conscientious objectors of that neighborhood with a telling argument.

It is up to the health authorities to lay down a standard of vaccination technic and to define accurately what is a "take," an immune reaction, or a failure. This standard should be nationwide in its application, and once promulgated should be enforced by the local health organizations. For years the Public Health Service has safeguarded the purity and potency of smallpox vaccine. Could it not with equal propriety standardize vaccination methods?

PHYSICIAN AUTHORS: DR. JOHN MOORE

When Dr. John Moore, the father of Sir John Moore, (hero of the Battle of Corunna, immortalized in Charles Wolfe's poem, *The Burial of Sir John Moore*) wrote his first novel, *Zeluco*, he issued this warning to the public: "Tracing the windings of vice and delineating the disgusting features of villainy are unpleasant tasks, and some people cannot bear to contemplate such a picture. It is fair, therefore, to warn readers of this turn of mind not to peruse the story of *Zeluco*." This warning, we are told, was issued in all sincerity, though if a similar warning in connection with a novel were issued today one would be justified in suspecting its purpose. At any rate, human nature in those days (1789) was no different from that of today, and so the warning was not heeded. Instead, *Zeluco* instantly became a best seller. It ran through several editions in England and Ireland and was translated into French. Then, like many another best seller, it sank into oblivion. Critics say that, as novels go nowadays, it was a pretty dull story and generally defective as a piece of literature. But although *Zeluco* was a third rate product, it has, as Thomas Spencer Baynes points out in the *Encyclopedia Britannica*, left an abiding mark on English literature through Byron's *Childe Harold*, which was in-

spired by *Zeluco*. "The character took great hold of Byron's imagination," says Baynes, "and probably influenced his life in some of its many moods, as well as his poetry. It is not too much to say that the common opinion that Byron intended *Childe Harold* as a reflection of himself cannot be cleared of its large mixture of falsehood with a study of Moore's *Zeluco*. Byron said he intended the *Childe* to be 'a poetical *Zeluco*,' and the most striking features of the portrait undoubtedly were taken from that character. At the same time it is obvious to everybody acquainted with Moore's novel and Byron's life that the moody and impressionable poet often adopted the character of *Zeluco*, fancied himself and felt himself to be a *Zeluco*, although he was at heart a very different man."

Mr. Baynes is one of the few latter day admirers of Dr. Moore's fiction. "In these days," he says, "*Zeluco* would be called a psychological novel; it is a close analysis of the motives of a headstrong, passionate, thoroughly selfish and unprincipled profligate. It is full of incident and the analysis is never prolonged into tedious reflections nor suffered to intercept the progress of the story, while the main plot is diversified with many interesting episodes." Dr. Moore wrote two other novels, *Edward* and *Mordaunt*, and several other books. *Edward*, in two volumes, and *Mordaunt*, in three, were both dull stories and neither as successful as *Zeluco*. Dr. Moore intended *Edward* to illustrate the admirable side of life, the reverse of *Zeluco*. George Saintsbury, one of the ablest of present day critics, says Moore's novels "lacked concentration and finish, and he is likely never to be read again as a whole."

Moore's first book was his *Views of Society and Manners in France, Switzerland and Germany* (two volumes), published in 1779, after he had spent five years on the Continent with Douglas, eighth Duke of Hamilton, who was in poor health. He followed this with two more volumes of *Views of Society and Manners in Italy* and in 1786 he published *Medical Sketches*, in two parts. The first part is physiological and its most original remark (says Norman Moore in *The Dictionary of National Biography*) are on the reflections and impressions from one nerve to another, illustrated by the fact that eating ice cream gives pain at the root of the nose. The second part treats, but with no great clearness, of several varieties of fever. Moore also wrote two volumes on the French Revolution, of which he was an eye witness, having gone to France in 1792 with the Earl of Lauderdale. He saw the disturbances of August 10th and the massacres of September 29th, and many other features of the revolt. His account of these events is set down in his *Journal During the Revolution in France from*

August first to December 15, 1792. The *Journal* appeared in two volumes, in 1793 and 1794, and was followed by two volumes entitled *A View of the Causes and Progress of the French Revolution*. Carlyle quotes Moore frequently in his history of the French Revolution, despite the fact that he disparaged Moore's reportorial ability. "As an author," says Carlyle, "Dr. Moore was more distinguished by the range of his information than by its accuracy or extent upon any particular subject, and his writings did not owe their celebrity to any great depth or originality of thought. . . . As a novelist he showed no extraordinary felicity in the department of invention, no great power of diversifying his characters or ease in conducting his narrative." Moore's other literary work included a biography of his friend, patient, and fellow physician, Dr. George Tobias Smollett.

Dr. Moore was born in Stirling, Scotland, in 1729, and was educated first at the Glasgow grammar school, after which he entered Glasgow University and at the same time was apprenticed to Dr. John Gordon, the surgeon to whom Smollett also was apprenticed. Beside attending the medical courses at Glasgow University he devoted himself to the study of literature, history, and philosophy. At the end of his apprenticeship, in 1747, he was made a surgeon's mate in the Duke of Argyll's regiment and saw considerable service on the Continent. After peace was declared he attended Dr. William Hunter's lectures in London, then went to Paris to continue his medical studies, returning to Glasgow in 1751 to become Dr. Gordon's partner. On his way from Paris he attended another series of Hunter lectures and took a course in midwifery. He practised two years with Gordon, and then with Hamilton, the professor of anatomy, but it was not until 1770 that he obtained his M. D. degree at Glasgow University. It was two years later that he started on the five year tour of Europe with the Duke of Hamilton. Upon his return to England he resumed practice in London. After many years' practice his health broke down and he went to live at Richmond, Surrey, where he died on January 21, 1802.

"Dr. Moore was sagacious as a physician and throughout his life had intense enjoyment in general observation and in every kind of good literature and good society," says Norman Moore (in the *Dictionary of National Biography*). "He was universally liked and most of all in his own house. He was well built and had regular features. Sir Thomas Lawrence painted his portrait and there was another portrait of him with the eighth Duke of Hamilton and Sir John Moore (his son) by Gavin Hamilton."

DEATH RETURNS

The examination of the mortality records of a community is not the most pleasant pursuit from a general point of view, and it is certainly not encouraging to one who has the progress of medical science and the advancement of health at heart. We do not refer here to errors as to "cause of death" nor to that always confusing "contributory," "secondary" or "intercurrent" factor in the taking off of the deceased. The former is too often puzzling and we must confess that we sympathize with anyone who becomes confused by these latter terms and have been longing to have someone render them lucid or replace them by a word or phrase of better defined meaning. One might find fault with the continued use of the expressions heart failure, debility, old age, and many others, if they were not such convenient and expressive terms and did not so readily cover our clinical ignorance. It is not so easy to give, instead, the name of a "definite disease" demanded by the registrar.

While the cause or causes of death should be given as carefully as possible we all have good reason for not always knowing just what brought the human motor to a stop. We seldom, however, have an excuse for not knowing the occupation and the exact occupation of the deceased. Moreover, when we fail to give these it is plainly evident, not only that we are not interested in, and do not comprehend, the full purpose of vital statistics, but it reveals the fact that we never made a thorough study of the case.

Occupation (or lack of it) is perhaps the greatest factor in the welfare of the human machine, and one cannot go too carefully into the work done by a patient and the conditions under which he works. It is not enough to know that a man labors in a factory, or that he is employed in a factory producing a certain product. There may be a dozen special occupations in this business with as many sources of wear and tear to the organism. It is not sufficient to ask a man where he works or in what department. He should be pinned down to the exact process he carries out and, if the lead seems at all promising, to an exact account of the materials and methods employed. It is of no use in diagnosis and of no service to statistical science to be able to place on the death certificate merely that the deceased was a carpenter or a musician or a painter. Without specification the student of certificates does not know whether the first stooped all day over a lathe in a dusty room or built houses, whether the second conducted an orchestra at ten thousand dollars a year or turned the crank of a hurdy gurdy, or whether the third was a prosperous landscape artist or a

worker in the lead laden atmosphere of some paint shop. Nor is it of any use to anyone to say that the decedent was retired, further than that retirement from work is often a dangerous procedure. If retired, retired from what? He might be a retired printer or a retired preacher. There is considerable difference when it comes to tracing and eradicating sources of occupational menace.

It is of great importance to be as exact as possible in giving the causes of death, but, with the exact occupation preceding death or for the major portion of life given, the death certificate becomes of far greater statistical value. Without this information it is of comparatively little use except for collecting insurance. The physician has no excuse for not making the death certificate a valuable document.

CHILD LABOR IN WISCONSIN.

Children in Wisconsin who are compelled to work have a distinct advantage over their young fellow toilers in other states, according to data set forth in the Biennial Report of the Industrial Commission (1918-1919), recently issued. All occupations except agriculture are covered by the child labor law of the state. Not only are working children thoroughly supervised, but those found physically disqualified are given medical service at nominal cost. Below fourteen years of age, Wisconsin children are given only vacation permits. Between the ages of fourteen and seventeen permits for regular employment are given on the basis of physical and educational qualifications. Close cooperation with the system of vocational and continuation schools is maintained by the staff of the commission and its agents throughout the state.

NOTICE TO OUR READERS.

The index for Vol. CXIII of the *NEW YORK MEDICAL JOURNAL* will be sent on the request of our subscribers. Those desiring it will kindly write to the editors.

News Items.

Pennsylvania Hospital to Be Enlarged.—The Pennsylvania Hospital, Philadelphia, is having plans drafted for a nurses' home, an outpatient building, a private patient building, a service building, and additions to the heating plant, laundry and laboratory.

New X Ray Tube.—Dr. Julius Lillienfeld, professor of physics at the University of Leipsic, inventor of a new x ray tube, gave a demonstration in the presence of Professor George Pegram and Professor Davis at the Department of Physics of Columbia University and before the New York Röntgen Ray Society. Experiments are being carried on with the new tube at Bellevue Hospital under the direction of Dr. I. Seth Hirsch.

American Chemical Society.—The annual meeting of the American Chemical Society will be held in New York, September 6th to 10th.

Cholera in Russia.—The Moscow authorities have officially admitted 47,779 cases of cholera throughout Russia and have also admitted that the number is on the increase.

Smallpox in a State Hospital.—Ten cases of smallpox were discovered in the State Hospital for the Insane at Waterbury, Vt. A new patient was said to have carried the disease to the hospital. The infected persons have been isolated and the entire hospital is under quarantine.

American Association of Obstetricians, Gynecologists, and Abdominal Surgeons.—The thirty-fourth annual meeting of the American Association of Obstetricians, Gynecologists, and Abdominal Surgeons will be held at the Hotel Statler, St. Louis, September 20th to 22d, under the presidency of Dr. Henry Schwarz, of St. Louis.

Reconstruction Assistant.—The United States Civil Service Commission announces an examination for reconstruction assistants in physiotherapy and occupational therapy. The salaries range from \$600 to \$960 a year, and maintenance. Applications will be rated as received until further notice. Applicants should apply for form 304, to the United States Civil Service Commission, Washington, D. C.

Death Rate of New York City.—According to statistics of the Department of Health, the deaths in New York city during the week ending July 23, 1921, were fewer than in the corresponding week of 1920. The figures are 984 deaths, giving a rate of 8.93 in 1,000 of population for 1921, against 9.21 in 1,000 a year ago. For the first thirty weeks of 1921 the death rate was 11.89 in 1,000, against 14.80 in 1,000 in 1920.

One Million Five Hundred Thousand Cancer Deaths.—The League of Red Cross Societies has just issued a report in which it states that in the four years from 1908 to 1912 cancer caused more than 1,500,000 deaths in civilized countries. The country which had the highest mortality between 1900 and 1919 was Switzerland, with 125 to 100,000 inhabitants. Holland and England come next, with about 100 in 100,000. The United States comes after England with a steady tendency toward increase in the number of cancer deaths. Italy has the smallest number of deaths from cancer.

Consultants to the National Pathological Laboratories.—Dr. George Dock, of St. Louis, Dr. Otto Folin, of Boston, and Dr. Ludwig Hektoen, of Chicago, have accepted appointments as consultants to the National Pathological Laboratories, New York. They will specify the methods to be used and keep the laboratories in touch with the most modern advances that will be useful in aiding the practising physician. Problems relating to the application of laboratory service to clinical medicine will be referred to Dr. Dock; Dr. Folin's advice will be followed in problems of blood chemistry and other biological subjects, and questions relating to tissue diagnosis, bacteriological and serological methods will be referred to Dr. Hektoen.

Johns Hopkins Hospital Fees.—The Board of Trustees of the Johns Hopkins Hospital has issued a dictum fixing the maximum fee for an operation in the hospital at \$1,000 and the maximum charge for attending a patient in the hospital at \$35 a week. The ruling applies to only part time professors and their assistants.

New Officers of Medical Association of Montana.—At a recent meeting of the association, the following officers were elected for the ensuing year: Dr. Wyman F. Andrus, of Miles City, president; Dr. Charles F. Watkins, Billings; Dr. Aloysius N. Dolan, Great Falls, and Dr. Percy S. Rennick, Stevensville, vice-presidents. Dr. Elmer G. Balsam, Billings, was reelected secretary-treasurer.

Cosmopolitan Cancer Research Society.—A new research laboratory has recently been formed in Brooklyn to study cancer and disseminate information as to the nature of the disease, its causes, methods of prevention, and treatment. The society will cooperate with federal, state and municipal health departments, hospitals, and all organizations through which education may be extended to the people.

Prevention of Rickets.—A committee was recently appointed in New York for the purpose of ascertaining the prevalence of rickets among children born of Italian parentage, in those nursed exclusively and in those fed artificially; to devise means of preventing rickets by various measures, such as the use of cod liver oil, sunlight and fresh air, diet, hygiene, etc., and to cure the condition after it has appeared. The committee is composed of representatives of the bureau of child hygiene of the New York City Department of Health and the Association for Improving the Condition of the Poor, and among its members are Professor H. C. Sherman, Professor Mary S. Rose, Professor Graham Lusk, Dr. Alfred F. Hess, Dr. Charles Hendee Smith, Dr. Louis C. Schroeder, Dr. Jules M. Blumenthal, Dr. Jacob Sobel, Mr. Bailey M. Burritt and Mr. John C. Gebhart.

Personal.—Dr. George E. de Schweinitz and Dr. John G. Clark, both of Philadelphia, will leave for Peking, China, on August 18th, to attend the installation of the new director of the Union Medical College, founded by the Rockefeller Foundation.

Lieutenant Colonel Harry L. Gilchrist, Medical Corps, United States Army, has been awarded the distinguished service medal for exceptionally meritorious and distinguished service while serving as chief of the delousing and bathing services of the American Expeditionary Forces.

Walter G. Campbell, assistant chief of the Bureau of Chemistry, Department of Agriculture, Washington, D. C., since 1916, has been made acting chief to fill the place of Dr. Carl L. Alsberg, who resigned July 15th. Dr. W. W. Skinner, chief of the water and beverage laboratory of the bureau since 1908, is designated as assistant chief.

Dr. W. C. Billings has been appointed director of inspection of immigrants at Ellis Island. He succeeds Dr. J. W. Kerr, who has been transferred to the Surgeon General's office, Washington, D. C. Dr. Billings has been executive officer twice since entering the United States Public Health Service in 1898.

Suicides in 1921.—In the first six months of the year 1921, there were reported to the Save-a-Life League 6,509 suicides of whom 4,527 were males and 1,982 females. In the first half of 1920, 2,771 suicides were reported in the United States, 1,810 males and 961 females. The average age of the male suicide is forty-three years. Unsettled economic conditions, with loss of employment and business failures, are blamed for the suicide wave which has spread over the country since the first of the year. Two hundred and twenty-five children ended their lives in the first half of 1920; the number has more than doubled this year. The average age of girl suicides is fifteen and of boys sixteen years.

Died.

ABBOTT.—In Brookline, Mass., on Monday, August 1st, Dr. Florence Hale Abbott, aged fifty-three years.

ADAM.—In Jersey City, N. J., on Thursday, July 28th, Dr. Clovis Adam.

BLOCKLINGER.—In Dubuque, Ia., on Wednesday, July 20th, Dr. Albert Herman Blocklinger, aged fifty-four years.

BROWN.—In New York, on Friday, July 29th, Dr. Helen Williston Brown, aged thirty-seven years.

BROWN.—In Parkersburg, W. Va., on Sunday, July 24th, Dr. Robert L. Brown, aged sixty-six years.

BRYANT.—In Berkeley, Cal., on Saturday, July 16th, Dr. John Bryant, of Independence, Mo., aged seventy-six years.

BURGIN.—In Philadelphia, Pa., on Sunday, July 31st, Dr. George H. Burgin, aged sixty-seven years.

CROSTHWAITE.—In Altoona, Pa., on Monday, July 18th, Dr. David Wilmot Crosthwaite, aged sixty-four years.

CROSTON.—In Haverhill, Mass., on Saturday, July 30th, Dr. John F. Croston, aged sixty-six years.

GRAY.—In New York, on Saturday, July 23rd, Dr. Herbert L. Gray, aged thirty-nine years.

HICKS.—In Mobile, Ala., on Monday, July 18th, Dr. Lamartine O. Hicks, of Jackson, aged seventy-two years.

HURLOCK.—In Philadelphia, Pa., on Sunday, July 24th, Dr. Frank I. Hurlock, aged sixty-two years.

LOMISON.—In Mt. Carmel, Pa., on Monday, July 18th, Dr. William A. Lomison, aged seventy-four years.

MCCAY.—In Sunbury, Pa., on Thursday, July 28th, Dr. Mary Anne McCay, of Northumberland, aged sixty-four years.

MOON.—In Philadelphia, Pa., on Sunday, July 24th, Dr. Rachael Tatnall Moon, aged forty-seven years.

MOORE.—In New York, on Sunday, July 31st, Dr. Edwin W. Moore, of San Diego, Cal., aged seventy-three years.

MUSGRAVE.—In New York, on Sunday, July 31st, Dr. Christopher James Musgrave, aged forty-six years.

SELDEN.—In Troy, N. Y., on Sunday, July 24th, Dr. Robert Selden, of Catskill, N. Y., aged seventy-three years.

SIMS.—In Memphis, Tenn., on Thursday, July 14th, Dr. Samuel C. Sims, aged fifty-nine years.

SMITH.—In Kingston, N. Y., on Saturday, July 30th, Dr. George De Forest Smith, aged sixty-nine years.

SWINBURNE.—In Rye, N. Y., on Saturday, July 23rd, Dr. George Knowles Swinburne, of New York, aged sixty-three years.

TODD.—In Cleveland, Ohio, on Sunday, July 17th, Dr. Frank H. Todd, aged seventy-two years.

TOOMBS.—In Lexington, Ky., on Friday, July 15th, Dr. R. Saunders Toombs, of Memphis, Tenn., aged seventy-seven years.

ULLRICH.—In Brooklyn, N. Y., on Wednesday, July 27th, Dr. Robert Matthew Ullrich, aged forty-six years.

VANDERHOOF.—In Phelps, N. Y., on Friday, July 29th, Dr. Frederick D. Vanderhoof, aged seventy-eight years.

WESTFALL.—In Dresserville, N. Y., on Sunday, July 17th, Dr. Helen M. Westfall, aged seventy-one years.

WHITESIDES.—In Indianapolis, Ind., on Sunday, July 17th, Dr. Lindsey L. Whitesides, of Franklin, Ind., aged sixty-one years.

WOOFER.—In Centralia, W. Va., on Wednesday, July 20th, Dr. James Vernon Woofler, aged forty-five years.

THE SYRACUSE CLINIC.

BY C. E. COON, M. D.,
Syracuse, N. Y.

Much has been said about group medicine since the close of the World War. During the conflict it became apparent that free collaboration of two or more specialist physicians brought quicker and happier results to all concerned. The immense amount of progress in each subdivision and redivision of medicine has rendered the individual specialist capable of correctly handling only a certain proportion of cases, and apart from medical advancement the conclusions of several men are less likely to be in error than those of a single practitioner.

Loose forms of group medicine have been practised for years, such as the calling of consultations, so-called hospital clinics, ward work, and in other apparent ways. Group medicine in the true sense

general surgery; Dr. T. H. Halsted and Dr. F. J. O'Connor, otolaryngology; Dr. A. C. Durand, ophthalmology; Dr. S. P. Richmond, dermatology; Dr. T. F. Laurie, genitourinary surgery; Dr. N. P. Sears, gynecology; Dr. C. E. Coon, orthopedic surgery; Dr. J. H. Burch and Dr. F. C. Rulison, roentgenology, gastroenterology, radium and electrotherapy; Dr. A. B. Siewers, neuropsychiatry; Dr. H. G. Locke, consultant neuropsychiatrist; Dr. O. W. H. Mitchell, consulting bacteriologist; Dr. R. K. Brewer, consulting chemist; Miss Mary B. Cooper, A.B., in charge of the laboratory. To these will be added other special departments and a dental diagnostician and surgeon will be included. Thus all the important departments of medicine and surgery and the specialties are represented.

A graduate of the Nitchi School is instructor in the teaching of lip reading for the deaf, and a competent instructor is in charge of corrective gymnas-

FIG. 1.—Syracuse Clinic, Fayette Park, Syracuse, N. Y.

implies much closer association, preferably all housed under a single roof and in more or less legal affiliation with one another. Thus there may be liberal use of one another's time and apparatus to the single end of securing an accurate, quick, and less expensive diagnosis. It is the most practical manner of making use of the principles of collaboration, and opportunities for research are afforded that do not obtain in individual practice. The Mayo clinic stands out as a testimonial of the truth of this statement.

The Syracuse Clinic is an association of physicians for the practice of group medicine. The partnership consists of Dr. T. H. Halsted and Dr. C. E. Coon, with fifteen physicians comprising the active staff of the clinic. They are as follows: Dr. W. A. Groat, Dr. E. V. Sweet, and Dr. C. E. McElwain, internal medicine; Dr. A. G. Swift and Dr. P. K. Menzies,

tics. A trained mechanic is in charge of the shop for the construction of various orthopedic devices. A force of trained nurses, secretaries, stenographers and a trained librarian complete the staff.

The site of the Syracuse Clinic building is an excellent one, on Fayette Park, close to the business centre of Syracuse. The colonial type of the structure adds dignity to its purpose. There are three large floors and a well lighted basement. A spacious reception hall on the main floor serves as a common waiting room and in addition to this the two corridors serve as waiting rooms. The offices are large and provide ample space for greater facility in work. The equipment of the various departments is very complete and in keeping with the latest advances in medicine.

In the x ray room various screens, filters and grids are constantly in use to improve the quality

of the picture work and there are offices equipped for the use of diathermy, high frequency, and other electrotherapeutics. A quantity of radium is owned by the clinic and its use is directed by an experienced physician. The examination rooms and operating room are tiled. The medical section is, of course, the largest, having six connecting offices. In this department there is also a room for the study of basal metabolism by the Benedict method. The large laboratory is completely equipped for clinical and research work. The well supplied library is a most useful room and in this daily consultations are held on the group and other cases following luncheon in an adjoining room.

GENERAL DESCRIPTION OF THE METHOD PURSUED
BY THE CLINIC IN THE DIAGNOSIS OF DISEASE
AND THE TREATMENT OF PATIENTS.

Diagnosis is the foundation of treatment. Effective treatment depends upon accuracy of diagnosis.

The majority of persons requiring medical treatment are suffering from some disease of a definite

FIG. 2.—General waiting room of the Syracuse Clinic.

nature, the diagnosis of which may be made by one physician or specialist. This class of patients may not need an exhaustive examination and it may not be necessary for them to be examined or treated by more than one physician. In this case the method of procedure is exactly as if the patient were consulting any competent doctor.

In the more complex cases, however, every available means of investigation may be required to reach a diagnosis. Various special tests and examinations are usually necessary and the services of a number of physicians, representing different specialties, the laboratory and x ray, all working in collaboration, may be needed before the nature and cause of the disease or affection can be made clear, in which event the method known as group diagnosis is employed. Briefly this method is as follows:

A comprehensive history of the patient's complaint is taken by the physician making the first examination, after which the patient is seen by such specialists as are required to examine the case. Laboratory tests of secretions, excretions, blood and the necessary x ray examinations are made. Written reports

of the findings of the different specialists and departments are furnished to the physician of the group having the case in charge. Following this, consultations of the doctors especially concerned in the case are held, and an opinion or diagnosis is reached.

After the examination is completed, if the patient

FIG. 3.—Laboratory of the Syracuse Clinic.

has been referred to the clinic by an outside physician for diagnosis alone, the patient will be returned to his own doctor with the opinion and advice of the clinic. If he has come for treatment he will be referred to the proper specialist for treatment of his particular case.

The organization of the clinic, then, is such that a patient may have to consult but one physician and be examined or treated by him alone, or the services of as many physicians as may be needed in any given case may be utilized for either diagnosis or treatment. The patients requiring hospital service are sent to one of the hospitals of the city with which the physicians of the clinic are connected.

FIG. 4.—Orthopedic shop of the Syracuse Clinic.

Periodical health examinations for the purpose of discovering early tendencies to disease or its presence are undertaken by the clinic, there being a very definite demand by persons, especially those over forty years of age, for the character of medical examination known as life extension service.

The expense to any patient will, of course, vary in accordance with the amount of time, labor, care and material expended. Patients consulting one doctor only would pay the ordinary fee charged by a specialist for similar services. In more complex cases, requiring group diagnosis, there is conservation of time, easy collaboration of the specialists, and unity of control. A single bill, which includes the services of the various physicians engaged in any given case is rendered by the clinic and not by the individual doctor. A flat fee is charged for group diagnosis and life extension examinations, while for treatments or surgical work the fees depend upon the work performed.

LONDON LETTER.

(From our own Correspondent.)

LONDON, June 11, 1921.

The Hospital Crisis—Sir James Cantlie on Tobacco—Notification of Venereal Disease—Maternity Endowment—Physical Education in Schools.

This unfortunately is a time of crises, of unwonted happenings, and like industry the hospitals seem to be in a state of chaos or more probably of evolution. Perhaps your readers may think that I dwell somewhat unduly upon the hospital question, but when it is considered that it is one of the most insistent questions of the hour, both from the point of view of the medical profession and of the general public, it is difficult for a writer on medical matters to evade it. At once it may be said that the situation is as bad and in many respects worse than ever. No solution of the problem appears to be in sight. Two letters contributed to the *London Times*, May 12th, from chairmen of two of the most important London hospitals will show more clearly how affairs stand than anything I can say. Lord Knutsford has been referred to in these letters previously. He is the chairman of the immense London Hospital, situated in the midst of the poorest district of London, and has made for himself a name throughout the length and breadth of the land for the manner in which he has kept the institution going despite the fact that its endowment is trifling. Indeed it has been for years the very type of a voluntary hospital. Lord Knutsford writes as follows: "Owing to the serious position of the London Hospital, the committee settled at their last meeting to close two hundred beds, and to cut down the out-patients by 35,000. The patients now occupying the beds will, of course, remain until well enough to leave, but no more patients will be admitted to them. The announcement has caused consternation in East London. This means that in a fortnight or so hence 200 beds in England's largest hospital will be closed and what adds to the tragedy of it is that there is today an accepted list of 761 poor people waiting for a vacant bed, whose illnesses have been recognized by the medical staff as curable only if they can get inpatient treatment."

The other letter is from the chairman of King's College Hospital, the hospital immortalized by the fact that Lister was a member of the staff. The letter reads thus: "About this time last year it became known that the voluntary hospitals in Lon-

don were faced with a financial crisis, and that unless some special grants could be made to them they would be compelled to close many of their beds. This disaster was averted, but the position today is unfortunately no better than it was twelve months ago, and there appears to be no prospect of immediate relief. So serious indeed has it become that at two hospitals a decision has already been taken to close wards, which will reduce the number of beds available by nearly 400, and it is certain that this example must be followed by others unless debts can be paid and larger income assured for the future. Hospitals have carried on in the hope that payment by patients, assistance from approved societies, or the institution by the Government of a general health scheme in which they could participate and be paid for services rendered would relieve them of their difficulties but, in fact, many of them are faced with great debts and can no longer gamble on hopes for the future. These debts were in some cases incurred or increased during the war. At King's College Hospital, in the years from 1914 to 1919, three quarters of the beds were devoted to military patients of whom nearly 31,000 were treated; but voluntary contributions and income from endowment exceeded the total amount paid by the War Office in those years by over £34,000, and in addition the hospital spent during the same period nearly £34,000 more than it received. I think it is clear that the Government received much more than it paid for, and I do not believe that voluntary effort would be discouraged if in such cases grants from public sources were made with the object of helping to extinguish the debt."

Although the prospect for the hospitals seems dark, there are some gleams of light breaking through the prevailing gloom. They received recently a large amount from the National Relief Fund as well as a goodly proportion of the surplus of something like £7,000,000 of the approved societies. But these are merely stopgaps. What is required is the evolution and carrying out of a scheme which will place them on a sound financial basis. Better organization is needed, closer cooperation between the hospitals and perhaps, above all, a well arranged pay system.

* * *

Sir James Cantlie seems to be endeavoring to rival the gloomy Dean of St. Paul's, Dean Inge, as a prognosticator of evil and a sayer of caustic albeit frequently pertinent phrases. He has within the past few months inveighed in no measured terms against many of the habits of the modern man and woman, which he regards as contrary to the laws of health. The other evening he addressed members of the tobacco trade on Tobacco and Health, at a conference in London. Sir James as a matter of fact, used mild language with regard to tobacco. He described it as a luxury, and hesitated to call it a physical necessity. But, in his opinion, it was none the worse for being a luxury. While he could not assert that it had done people any good physically, neither could he state that it had done any harm. According to Sir James, tobacco is one of the four social poisons, the other three being tea, coffee and alcohol, and it was the last of the four

to be introduced. Alcohol was known by the first man, and it would go on for ever and ever. He hastened to explain, however, that the juice of the grape was one thing, and alcohol as we know it today, another. Tobacco might cause trouble now and again, but it was not nearly so dangerous as alcohol. If a person gave up tobacco for three days, he would free his body of every particle of nicotine. Taken at the first blush, tobacco was the least harmful of the social poisons, and tea was the most harmful. The speaker unreservedly condemned cigarette smoking and said that when he was a boy it was only the villain of the piece who smoked a cigarette. Cigarette smoking was a habit that came from the East. The French, who were early cigarette smokers, were taught by the Arabs. He considered that cigarette smoking stained one's inside worse than it stained one's skin and he proceeded to point out the dangers of inhalation which, he said, tended to make the lungs leathery. He had heard of a man who smoked an ounce of tobacco every day of his life, and yet lived one hundred years. If that man had smoked an ounce one day and half an ounce the next day, he would not have lived so long. The smoker tuned his heart to a certain amount of nicotine, and he should be very regular in the amount of tobacco he smoked. Referring to smoking by women, Sir James pointed out that woman-kind had long been addicted to the habit.

* * *

Notification of venereal disease has been proposed more than once in this country but the proposal does not seem to find favor with the medical profession as a whole. A Dr. James Hamilton in a letter contributed to the *Medical Press and Circular*, May 11, 1921, pertinently points out that were it possible to spy out all women, professional and otherwise, with venereal disease and segregate them, there would be a rational ground for compulsory notification, but as that is impossible, compulsory notification would only tend to self-medication, as women especially would not consult a doctor if notification were compulsory and would treat themselves.

* * *

There has been a good deal of discussion recently on the endowment of motherhood and undoubtedly with regard to the welfare of the race such a scheme has much to be said in its favor. But it also has several obvious drawbacks. At the League of Nations Labor Convention, held some little time ago, it was proposed that the State should support women industrial workers before and after childbirth. Sir Alfred Watson, the British Government actuary, urged many objections to the scheme from the financial viewpoint. He estimated that of approximately 4,520,000 women of childbearing age belonging to the industrial classes, about 460,000 would be entitled to benefits under the convention. As regards single women, about half of the unmarried mothers are domestic servants who are excluded from the scheme. Taking married and single women together, the number of births among those industrially employed would probably be about 120,000. It is further pointed out that the title to benefits is governed solely by the employment of the mother, and is independent of the position of the

father. From this it would appear open to question whether in practice the benefits could be limited to employed women, and it does not seem unreasonable to assume that there would spring up an immediate and insistent demand for the extension of the benefits to mothers of every social class irrespective of any question of employment. The proposal is that in every case where the grant becomes due, benefit shall be paid for six weeks following confinement and that it shall be open to the woman to give up employment at any time within six weeks of the expected date and commence to draw benefit forthwith. This implies twelve weeks' benefit in each case. A uniform rate of benefit is not laid down, but the amount is to be determined separately in each county. Assuming that the benefit was fixed at no more than twenty shillings a week, the cost for each woman would amount to £14 including, say, £2 for medical expenses. On the assumption that effective means of protection could be devised the cost of the scheme is estimated at about £1,700,000 a year.

Sir Alfred Watson points out that this estimate is subject to two conditions: 1. That the benefit did not draw into the labor market a large number of married women who otherwise would never have sought industrial employment. If this should happen the cost might easily be doubled. Other untoward consequences would also follow. Competition for work would increase unemployment, promote casualization and, in the long run, lower wages. 2. That the provision of the new benefit was not followed by an increase in illegitimacy. The provision of an unconditional subsidy to maternity of employed women, represented by a benefit of several pounds might have reactions which should not be overlooked. If the benefits were universal at £1 for each birth the cost would be over £15,000,000 a year.

* * *

Women appear to be invading what used to be deemed the especial realms of men, more and more as time goes on. There has been recently quite a heated discussion in the public press regarding the desirability from the health viewpoint of girls taking up very strenuous games and physical exercises as part of their training. Opinions differ somewhat widely on the subject, but the general view seems to be that exercises of a vigorous nature do most girls good, but that they are not suitable for women. Now educational authorities here are entrusting women with the physical training of boys. A strong protest against this new departure was made at the conference of the National Association of Schoolmasters, held at Cardiff recently. Mr. G. K. Sanderson, of Leeds, said that educational authorities throughout the country were appointing women to take charge of physical training, but by far the worst offender was the Board of Education itself. That board had eleven inspectors in that branch of education. The head of the department was a man, but of the remaining ten inspectors in charge eight were women. If women were not fitted for the physical instruction of boys, how much less were they fitted to supervise the men who were doing the work.

Book Reviews

SEX IN HYSTERIA.

Das Geschlechtsleben der Hysterischen. Eine medizinische, soziologische und forensische Studie. By Dr. med. PLACZEK, Nervenarzt in Berlin. Bonn: A. Marcus & E. Weber's Verlag, Dr. jur. Albert Ahn, 1919. Pp. 264.

This is a book to hold the reader from beginning to end. In fact, the brief foreword with its few pointed sentences rouses an eagerness to enter into the variety of material which these few words promise.

There is a special clearness of style on the part of the writer. He is never verbose nor extravagant of detail but strikes that most happy balance which comes of abundance of well mastered material presented with a commanding power of expression. He has a keen eye for facts and a broad basis of judgment in handling men. The book becomes a literary as well as a strictly technical treatise upon hysteria. It goes to prove indeed that hysteria, participating as it does in every walk of life, must needs be treated in that broader relationship which constitutes also a literary balance in writing. It suggests a still further truth, and that is, that the sex life is no narrow technical subject but extends itself into every phase of life and its discussion, even as related to one particular form of mental disturbance, is bound to take wide account of life.

The one ground on which one might quarrel with the writer lies just here. The quarrel need be no bitter one for Placzek has gone much further than half way to meet his critic. One only wishes that so progressive a thinker and observer had opened his eyes just a bit more widely. In reading his book carefully one fails to find him bound in actuality to any limitation of the sexual etiology or manifestation of the sexual as a factor to be considered in hysteria. Yet he repeatedly asserts his disbelief in the sexual as the complete etiology concerning hysteria. In this he frankly states his differences with Freud and his followers. He comes so close, however, to Freudianism, so hospitably accepts much of its service and its theory, one feels that only a little more understanding is needed. This, however little, is important, for he makes a mistake that is common in not sufficiently comprehending how all pervasive sex is in the sense in which Freud uses it, not alone in its more limited sense, but also in its polymorphous manifestations as it underlies and creates hysterical reactions. Placzek does not quite grasp the concentrated dynamism which underlies life's manifestations and which must necessarily be inseparable from the sex pouring through it and really constituting it.

Yet no criticism of Freud has appeared more sanely fair than this of Placzek. He evinces no emotional resistance which prevents a calm survey of the work Freud's theories have accomplished. One of his brief and by no means antagonistic expressions of disagreement reads thus: "One may take what position one will in regard to the Freudian theory; one may complain of its outgrowths, which are especially to be laid to Freud's disciples;

one may regret its onesided pansexualistic interpretations; nevertheless it has been thought out by a profound, intellectually gifted thinker. It has already given fruitful incentive in many directions, it has brought deep and dark phenomena closer to the understanding and, what is none the less important, it has shown the significance of sexuality in a manner that is awakening medical science from its fixation upon a too long exercised ostrichlike policy toward everything sexual." There are many other similar expressions of appreciation for the service Freud has rendered the theory of hysteria.

The book also has a positive value of its own. It embodies a rapid survey of the theory of hysteria throughout the history of medicine with reference especially to the swinging back in most recent times to the ancient conception that hysterical manifestations were somehow related to the sex life. Now, the writer insists, this is rightfully the position to be taken and it can be taken more fully than was possible in earlier times. He proceeds to show how the recognition of this relationship is inevitable in a review of the facts of the manifestations of hysterical characters whether viewed purely from clinical experience, or in cases involving legal situations. He quotes a number of cases which at various times have come prominently before the public and shows the farreaching sexual involvements in each one as well as the strong sexual features in the individual's makeup. There is an enlightening discussion of the relation of witchcraft to the sexual constitution manifested in the hysteric both in the past history of witchcraft and in the present day manifestation in hallucinatory or other forms of phantasy of the same factors which earlier led to belief in witchcraft.

Special chapters are given to those phenomena which have particular legal bearing, such as the pathological lying impulse or that of stealing, useless purchasing, and so on. More individual clinical symptoms get a somewhat briefer mention but are passed over comprehensively although rapidly. Two sections deal respectively with the hysterical woman and the hysterical man in their typical manifestations. Chief emphasis is laid upon the social and legal bearing of hysteria and the importance from these viewpoints of recognizing with full comprehension the pervasion of the sexual through all these relationships. For this reason there are important chapters dealing with definite forensic questions as related to hysterical individuals.

The whole work is stimulating to thought. It is instructive in the history of the hysterical theory as understood by its various chief exponents. The author has reviewed these different expositions, particularly of his contemporaries, with free inter-spersion of his own valuable comments. He has opened the way to wider interest in the subject and he awakens interest in its still more intensive study in all directions. Chiefly does he demand the attention of his readers to the seriousness of the

sexual aspect of the question which he constantly holds before them. He has certainly opened rather than blocked any avenue of further thought or research here, even though he himself has pursued it more in the field of effect than of cause. If he penetrated the latter more completely perhaps he would be compelled to a fuller acceptance of Freud's more sweeping position. It is no small service, however, to impress upon the medical world the more obvious facts in the field of results of sex factors because even these, as Placzek has said, have been strangely neglected.

DISEASES OF NOSE AND THROAT.

Diseases of the Nose and Throat. By HERBERT TILLEY, B. S. (Lond.), F. R. C. S. (Eng.), Surgeon, Ear and Throat Department, University College Hospital, London; Surgeon, Ear and Throat Department, King George's Hospital; Teacher of Laryngology and Otology, University of London; Laryngologist to the Radium Institute, etc. Fourth Edition. With Seventy-four Plates and Numerous Text Illustrations. New York: Paul B. Hoeber, 1920. Pp. xx-844.

The author and publisher have combined to present a volume of unusual excellence, both as to text matter and appearance. This is a manual belonging to a *Practical Series*, and therefore the author devotes most of his attention to the subjects of symptoms, diagnosis and treatment, although there is no evidence of neglect in the consideration of etiology and pathology.

Old chapters have been completely or partly rewritten for this fourth edition, and new chapters have been added on certain affections of the trachea and esophagus, intranasal dacryocystotomy for the relief of suppuration within the lacrymal sac, and a description of the intranasal routes employed in operations for pituitary tumors. Greater attention also has been given to postoperative treatment, than in previous editions. The chapters on the tonsils are carefully written and the teachings generally are distinctly conservative in character. The author considers chronic tonsillitis in children a menace, and believes the possibilities for evil are greater than the probabilities of danger incident to the removal of the tonsils, while the difficulties, risks and complications of operative intervention increase with the age of the patient. There is a good chapter on endoscopy of the breathing passages, well illustrated. The drawings throughout are clear and plentiful.

LIGHT AND RADIANT ENERGY.

Light By FREDERICK BOOTH, Author of *Radiant Energy and the Ophthalmic Lens*. Introduction by WHITEFIELD BOWERS, A. B., M. D., Formerly Major, M. C., U. S. A. South Bend, Ind.: Frederick Booth, 1921. Pp. 15.

Radiant Energy and the Ophthalmic Lens. By FREDERICK BOOTH. Introduction by WHITEFIELD BOWERS, A. B., M. D., Formerly Major, M. C., U. S. A. Two Hundred and Thirty Illustrations. Philadelphia: P. Blakiston's Son & Co., 1921. Pp. xxvii-226.

It is easy to pick flaws in theories more or less tentatively advanced to explain phenomena which are not understood; it is quite a different matter to correct those flaws, or to construct a new and better theory. The author of *Light* has done the first, but has not attempted the second. If he has advanced a constructive idea, it has escaped the reviewer.

In the second book, one of 211 pages, excluding the index, the reviewer has vainly sought for something new. The writer says: "In order to obtain a better understanding of optics, I have included radiant energy. These sections describe the ether theory; also actinic light, electrical heat, cathode, x ray, alpha, beta, and gamma rays; sound and water waves; also waves in a rope. Harmonic motion is described. The various theories of light are explained." All of these things are mentioned, but the best that the reviewer can make of the book is that it contains a lot of facts well known to every student of optics, stated curtly and not always in the clearest manner. It is not well written. The definition of radiant energy on page 6 is a meaningless jumble of words as it stands, though the reader can easily understand what is meant. On page 120 he says: "In testing the refraction, unless the ciliary is relaxed (a cycloplegic is positive), the optical condition of an eye cannot always be ascertained." The book is profusely illustrated and references to other writers abound, but it will give little help to the student of ophthalmology.

WAGNER IN ENGLISH.

The Pertinent Wagnerite. By B. M. STEIGMAN. New York: Thomas Seltzer, 1921. Pp. 127.

This title introduces a series of brief essays of the sort that are gradually recalling us from our hasty reactions when the event of war precipitated convictions out of emotion without the cooling aid of reason. The writer pokes fun at us over the head of a pretended serious proof of Wagner's prophetic powers and thoroughly pro-Ally spirit. He shows Wagner as enlisting the personnel of *Der Ring des Nibelungen* to foretell the events of the war and to preach to the last detail all the gospel of the new democracy rising upon the downfall of kings. Then Steigman goes on to show what remarkable similarity in action we produced to the actions of destruction for which the enemy were decried when we stormed against the production of the works of this master of art. He goes further and reveals in some detail the mutilation which the English translation has perpetrated upon these monuments of thought and art. He seriously sounds a note of warning of the permanent effect this is likely to have upon our artistic taste as it silently condones us in that slipshod habit of art of which we are guilty. There is more of this sort of half fun making, half seriousness, recalling us to ask ourselves what we really have been about and what is our responsibility toward the future. This is not alone in regard to these works of art but to the justice of calmer thought and action as a matter of truth to ourselves both artistically and morally.

The writer has pertinently—we borrow his word—laid his finger upon some of the psychology at work within us, some of those deeper facts from a too clear knowledge of which we squirm away under cover of mob sentiment. Now that the war is over and Wagner has come back, even in a mutilated condition, it will not hurt us to think at least a little in regard to our psychology as a group of facts. Steigman might have been a little more clear in his statements, then his fun and his seriousness would

both have gained in pungency. Nor has he been quite fair to Wagner. It does not matter that he has indulged in a completely worked out interpretation of his own in regard to the Ring. A pretty one it is too in the face of recent events. A master's works remain quite unaltered by any such borrowed use of them. Wagner might have been impatient with any such surface interpretation but he did have a ready humor as a personality even though he did, as Steigman reminds us, allow the swan to be borne out on a flimsy litter. But there are places where Steigman has touched upon deeper psychic meanings and we do not think he has always been happily correct. The attempt to put a temporizing explanation warps the appreciation or realization of some of the more fundamental truths. Wagner seized with a threefold grasp profound human truths which have been and will be while humanity shall stand. Steigman is right that none of his forms of expression, words, music, characterization can be divorced from the others. Beneath and within them lie the psychic truths themselves, deeper than any fun, than any partial or specially applied interpretations, deeper than all the scorching flames of war.

BERGSON'S PHILOSOPHY.

Bergson and Future Philosophy. An Essay on the Scope of Intelligence. By GEORGE ROSTREVOR. London: Macmillan & Co., Ltd. Pp. 152.

Rostrevor in his criticism of Bergson reasons in an interesting fashion even though his conclusions are not conclusive. He has built a superstructure of philosophy on a flimsy base for his entire concept of instinct is altogether too mystic. Philosophers of his type, who are earnestly seeking the truth and are forced to accept rational substitutes, would do well to look upon instinct as unconscious memory. This would remove much mysticism and enable Rostrevor, Bergson, and a host of his followers better to understand the past and also the consciousness of the present. They have given us many invigorating ideas and have clarified many obscure points and it is to be regretted that they cannot accept the more simple yet more workable hypothesis of unconscious memory. They could then divide it into the phylogenetic and otogenetic unconscious—keeping it separate from the conscious. Perhaps we are asking too much of them, forgetting for the moment that they profess to be philosophers.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

RACKEMANN, M.D., Assistant in Medicine in the Harvard Medical School; Assistant in Medicine in the Massachusetts General Hospital, Boston, Mass. Philadelphia and New York: Lea & Febiger, 1921. Pp. xii-194.

DISEASES OF THE SKIN. A Practical Treatise for the Use of Students and Practitioners. By OLIVER S. ORMSBY, M.D., Professor and Head of the Department of Skin and Venereal Diseases Rush Medical College (in Affiliation with the University of Chicago); Dermatologist to the Presbyterian, St Anthony's and West Suburban Hospitals, and the Home for Destitute Crippled Children. Second Edition, Thoroughly Revised. Illustrated with Four Hundred and Forty-five Engravings and Four Plates in Colors and Monochrome. Philadelphia and New York: Lea & Febiger, 1921. Pp. xiv-1166.

Practical Therapeutics

PARAFFIN TREATMENT OF BURNS.

By HARRY COHEN, M.D.
New York.

Attending Surgeon, Peoples' Hospital.

About ten years ago it was my privilege to treat three cases of extensive burns. The first was in a woman thirty years of age, who had received a third degree burn on her chest and back from the sudden outburst of flames after pouring kerosene into a stove to brighten the fire. She was sent to a hospital where she received the open air treatment. Healing took months, and resulted in a very painful keloid formation of the whole back and chest, which lasted for years. The second case was a severe scalding with boiling water of a considerable part of the body in a little child, who died on the third day, in spite of active treatment. In the third case, a child had sustained an extensive burn of the body and had been treated with picric acid for about a week. The child was delirious and very toxic. A striking feature was the condition of the urine, which was scant and of a dark color. The picric acid was discontinued, boric acid solution applied and constitutional treatment vigorously pushed. This child recovered, but the constitutional symptoms were always marked. These experiences caused me always to dread treating extensive burns. In reviewing the literature previous to the last few years, similar experiences and results appear to have been the rule.

Recently a patient with an extensive third degree burn came under my observation. The paraffin treatment was applied with an excellent result. The paraffin treatment will most likely be the method of choice in the future.

PROGNOSIS.

Leale (1) sums up the prognosis in burns, as follows. In first degree burns if two thirds of the body is burned or in second or third degree burns if more than one third of the body is burned, especially in adults, the prognosis is bad, usually fatal. In children even less area is necessary for a terminal result. With many exceptions this has been the general experience.

PATHOLOGY.

In a thorough review of this subject, Weiskotten (2) discusses the possible causes of death that had been advanced as follows:

1. Toxins acting in the body after extensive burns of the skin.
2. Loss of the function of the erythrocytes.
3. Production of thrombi.
4. Severe affection of the nervous system.

Bardeen (cited by Weiskotten) performed five autopsies on children who had died in a few hours after being burned and found early changes in the lymphoid tissues of the body and parenchymatous degeneration of the liver and kidneys.

Weiskotten (3) performed ten autopsies in burn cases, five in adults and five in children. The ages ranged from nineteen months to sixty years. The

deaths occurred from a few hours to twenty days. In none of the cases was there charring. His findings may be called authoritative. There was a uniformity of pathology in all cases. He observed the main lesions in the adrenals. These were swollen, deep red and on section showed congestion of the blood vessels and minute hemorrhages. The condition of the cells resembled the appearance of the liver in chloroform poisoning. In the spleen and lymph nodes there was edematous swelling especially of the germinal centres. The changes in the spleen and lymph nodes suggest that the changes are due to the presence of a poison in the circulating blood. In the heart, there was distinct hyaline degeneration of the fibres, the same as is seen in deaths from diphtheria, scarlet fever, and severe toxemias. The kidneys showed small fibrin thrombi. In the gastrointestinal tract small hemorrhages of the mucosa and punctate ulcers of the stomach were present. These findings, especially in the adrenals, will explain the sudden death and also many of the early symptoms that so many have called attention to, such as shock and fright.

METHODS OF TREATMENT.

The treatment may be divided into two groups: the old or ordinary method, and the new or paraffin.

A brief description of some of the popular and fairly well sponsored forms of treatment for burns other than paraffin are carron oil, wet dressing, open air, continuous bath, ointments, adhesive strips and rubber tissue strips.

Carron oil is a distinctly popular remedy both with the general public and some physicians. It is, however, universally condemned by the majority of surgeons who treat many burn cases because it almost always infects the wound.

Ravogli (4) in a paper read at the sixty-sixth annual session of the American Medical Association described the various forms of treatment then in vogue. He laid considerable stress on the value of wet dressings of aluminum acetate. The wound should be cleansed and wet compresses applied. Although this treatment has many advantages over other methods, there are several disadvantages, viz. the difficulty of keeping the gauze saturated, and of drying in places resulting in adhesions forming between the gauze and tissue. Haas (5) who advocated the open air treatment, in speaking about the other forms of dressings, says: "The terrors of the one waiting for the next dressing and the shrieks which accompany such a dressing are not easily forgotten." Also from another surgeon: "The removal of gauze which becomes enmeshed in the burned surfaces and granulations is a very painful and barbarous procedure and should be condemned." (Sherman, 6).

The continuous bath treatment, as its name implies, consists of placing the patient in a tub of warm water and keeping him there continuously until cured. This has no special advantages over other methods, and is difficult to carry out.

Picric acid used in one per cent. solutions as wet

dressings has many exponents and undoubtedly possesses many excellent healing qualities, but it stains everything yellow, and in the case originally described possibly many of the toxic symptoms were due to the absorption of the picric acid.

As for ointments, there are countless numbers of them in use, boric acid being the one most frequently employed. Others are salicylic acid, resorcin, dermatol, and zinc oxide. Although each has some good qualities, they are relatively expensive, require considerable gauze, are not easy to handle, stick to the tissues, and do not prevent ugly scars and contractures from forming.

The open air treatment, first sponsored by Haldor Sneve (7), consists of placing the patient in bed and leaving the burned parts exposed to the air, the other parts of the body being well covered. In warm weather cheese cloth or mosquito netting is placed over the bed to keep flies from the wound. Herrman (8), in addition to exposing the parts to the air, makes use of a dusting powder, preferably boric acid. Haas who advocates the open air method says: "To be sure, this method of treatment does not create a pleasant view. The odor and appearance of the wound are two objectionable features as is also the tendency of the patient to pick off the scabs." A serious objection, however, to this method of treatment consists in the disfiguring scar formation which frequently follows.

Parker (9) treated burn cases with adhesive plaster strips about one inch wide and slightly overlapping one another, the purulent discharge underneath the plaster making removal easy. He also applied casts and other apparatus to prevent contractures.

A method that for a time proved popular simulated the adhesive strips, using instead sterile rubber tissue or silver foil strips. This treatment was advocated by Leale. In both these methods scar formations very frequently follow.

THE PARAFFIN TREATMENT.

We now come to the paraffin treatment. This method was first advised sixteen years ago by Barthe de Sandfordt, and although the results appeared satisfactory, he was unable to popularize the treatment. The war presented a great opportunity for its use, however, and as the results were very satisfactory, its use was popularized. It was introduced into this country largely by William O'Neill Sherman who gave a thorough description of the preparation and its application.

Barthe de Sandfordt called the preparation he used ambrine (a compound of paraffin and resin). The two main reasons why it failed of popular approval in this country were, first, its recommendation for all kinds of diseases and, second, that the preparation was secretly patented and highly commercialized. During the war when de Sandfordt treated thousands of cases of all degrees of burns with ambrine, it was very evident that the patients when having their wounds dressed suffered no pain and recovered very rapidly with fewer scars and contractures. "Frightful disfigurement and loss of function were practically eliminated." (Sherman).

The paraffin does not cure, it simply acts in a mechanical way allowing nature to heal under con-

ditions favorable to repair. It excludes the air, maintains a constant temperature, and forms a protective dressing. It "serves as a superstructure or scaffolding to new epithelium which rapidly regenerates. The dressing serves as a poultice and cast. A secretion soon forms under the dressing which makes it easy to remove without pain, or bleeding or destroying the new regenerated epithelium, thereby facilitating the healing without apparent contracting cicatrices and without causing functional disability." (Sherman).

METHODS OF APPLICATION.

Briefly stated, the method consists of the following: Careful and gentle cleansing, removing all blebs; drying; paraffin layer; layer of absorbent cotton; paraffin layer; heavy dressing; bandage.

The practical method of its application may be more fully described in the following way. If the patient is seen immediately following the burn, the paraffin is applied at once. The paraffin preparation, either ambrine, redintol, parresine, stanolind or other preparations of which there are many on the market, is placed in a double jacketed atomizer and heated until the paraffin preparation is liquified. It is then sprayed over the burn, going beyond the margin about one or two inches. A thin layer of absorbent cotton or gauze is then spread over the wax film and the paraffin again applied, covering the cotton. The latter application is made by means of a camel's hair brush, as with this the area is covered more quickly. If the patient is confined to bed, that is all that is necessary. If ambulatory, a heavy layer of absorbent cotton is applied and then a bandage. The burn must be dressed daily, when a considerable discharge of seropus will be found under the paraffin, loosening and lifting it up and making its removal easy and painless. Each subsequent dressing is a repetition of the first. The pus does not cause any constitutional disturbances and in fact is a help in that it facilitates the removal of the paraffin cast. Where pus is too profuse or where absorption symptoms occur (fever, redness, and swelling) the paraffin treatment is discontinued for a day or two and the Carrel-Dakin solution applied. Chemical, x ray, electrical, and all other kinds of burns are amenable to this treatment.

Cassellberry (quoted by Sherman) treated seventy-five cases from a munitions explosion and had excellent results. His observations were: relief from pain, patient cleaner and more comfortable, fewer scars and contractions, skin grafting rare, more rapid healing, and he believed the method to be superior to other methods commonly used.

Behney (10) calls attention to the treatment of exuberant granulation tissue which is encouraged by this treatment. He says that granulations become vigorous and healthy and are controlled by pressure. He warns against the use of silver nitrate, because, if used, the healed skin will not be smooth. Although grafting is minimized, still in extensive burns he advises early grafting, usually in about three weeks.

The only disadvantage that Beiter (11) found was that more time and patience were required to apply this treatment. He also found that furuncles developed less frequently.

Hudson (12) voiced the sentiments of many when he objected to ambrine because it was patented, composed of a secret formula, and commercialized. However, many of these objections have since been overcome. An excellent and inexpensive formula devised by Max Kahn (13) is:

Paraffin	70.0 gm.
Liquid petrolatum, U. S. P.	3.0 c. c.
White beeswax	10.0 gm.
Rosin	7.0 gm.
Resorcin	0.2 gm.
Sudan III	0.05 gm.
Alcohol (95 per cent.)	10.0 c. c.

Other formulæ are given by Sollman (14).

Emerson (16) objected to the paraffin treatment, stating that he could not heal one case in twenty-three, claiming among the disadvantages that the wound was covered with a sealed dressing, that a copious seropurulent exudate was present on every dressing removed, and that there was no way of controlling the temperature of the wax. To answer these objections briefly, the seropurulent discharge is an advantage because it does not produce absorption symptoms and allows the paraffin to be removed painlessly, and if the paraffin is applied with an atomizer, there is no need of controlling the temperature of the wax as it is impossible to burn the patient.

The constitutional treatment depends upon the

COMPARISON OF THE THREE CASES.

	Girl	Boy	Mrs. K.
Extent of burn	Entire back from neck to gluteal folds, plus two arms.	Entire back from neck to gluteal folds, plus neck, one arm and hand.	Entire back from neck to gluteal folds, plus one arm
Treatment	Modified open air	Ointment adhesive strips	Ambrine
Duration of stay in hospital	Seven and a half months	Seven months	Three months, one week
Length of time of subsequent dressing	Seven and a half months	Still being dressed (1-15-21)	One month
Total duration of treatment	Fifteen months	Fifteen months plus	Four months, one week
Skin grafting	None	One year ago	None
Result	Considerable scarring and keloid formation	Ugly unsightly scarring.	Slight scarring

condition of the patient and consists of giving an initial hypodermic injection of morphine when indicated, stimulations with strychnine, and looking after the kidneys and intestinal tract.

The case reported below has two interesting features associated with it. In the first place, there were three persons burned at the same time and to about the same extent, but to each different treatments were applied. In the second place the condition of my patient was complicated by the presence of a large stone in the right kidney.

CASE.—Mrs. S. K., thirty-five years old, referred to me by Dr. J. Ruchman, was burned when her house set on fire during the early hours of Sunday, October 19, 1919. She and two others who were burned at the same time were removed to a hospital. The burns in each case were of about the same extent and all of the third degree. On the third day the patients were removed to different hospitals and in each case a different method of treatment was applied. One patient was treated with ointments for two or three months, following which the paraffin treatment was instituted for about a week and then given up (not a fair test), and for the rest of the time the treatment consisted of adhesive plaster strips. The second was treated by the open air method, and in addition was given warm baths about three times a week. These two patients were children, one thirteen years of age, the other ten.

The third patient was treated the first two days with wet dressings, and on being admitted to the Peoples' Hospital, was placed under my care. The first unpleasant task was to remove the gauze, which was painful. She was immediately placed under the paraffin treatment (ambrine preparation) according to the method previously described. The dressings were changed daily and gave her no pain. Originally the dressings were very tedious, later they took less time. There never was any constitutional disturbance. The result was excellent. The extent of the burn was as follows: The back of the left arm to elbow, the entire back, both buttocks, left thigh, left leg and left foot. Altogether she was in the hospital thirteen weeks, which seemed a discouragingly long time. She had to come for dressings to the office for four weeks more. A stubborn bit of granulation tissue on the shoulder required treatment during all this time.

About seven weeks after the accident, while still in the hospital for the burn, she had an attack of acute nephrolithiasis. Cystoscopy was impossible owing to the burned condition of her back. A röntgenograph showed a large stone, the size of a grape, in the parenchyma of the right kidney. On account of the burns she at first refused operation, but after suffering violent pains for a week, she consented, and on December 17, 1919, I did a nephro-

tomy and removed the stone from the parenchyma of the right kidney. She made an uneventful recovery and was out of bed in two weeks.

The following conclusions may be drawn from comparing these three cases:

1. Enormous time saved.
2. Skin grafting not necessary.
3. Dressings painless and comfortable.
4. Minimum scarring. In my case also, the presence of a serious kidney complication was possibly influenced for the better by this method of treatment.

NEW LARYNGEAL SPECULUM.*

By HENRY LOWNDES LYNNAH, M. D.,
New York.

The long slanting end anterior commissure speculum shown in Fig. 1 has been found very useful for the inspection of the larynx in adults, and also for the removal of tumors from the anterior com-

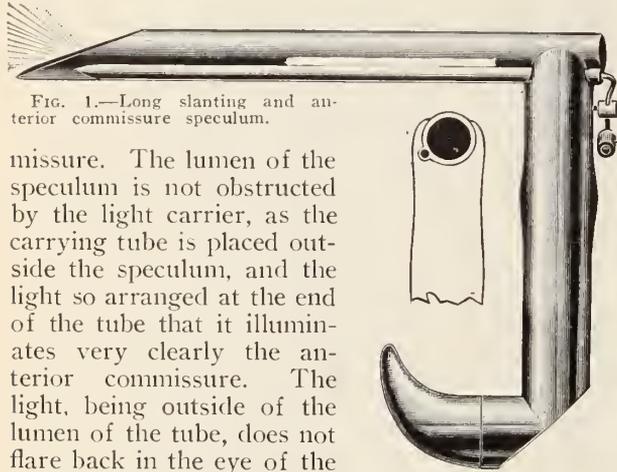

FIG. 1.—Long slanting and anterior commissure speculum.

missure. The lumen of the speculum is not obstructed by the light carrier, as the carrying tube is placed outside the speculum, and the light so arranged at the end of the tube that it illuminates very clearly the anterior commissure. The light, being outside of the lumen of the tube, does not flare back in the eye of the operator. The speculum is also useful for upper esophageal examination in children.

The ovoid laryngeal speculum for infants and children (Fig. 2), on account of its ovoid shape, is

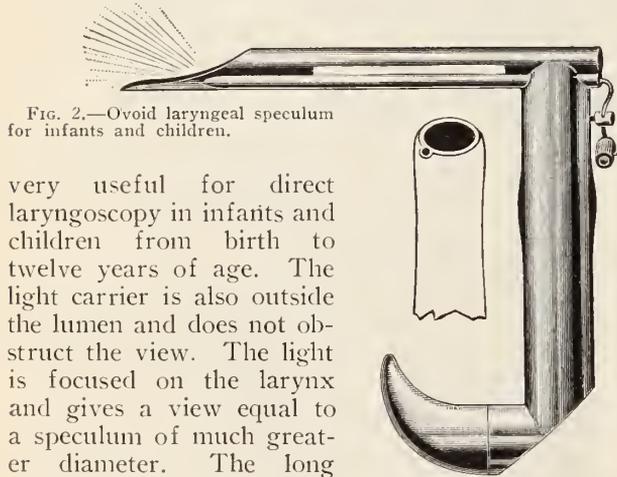

FIG. 2.—Ovoid laryngeal speculum for infants and children.

very useful for direct laryngoscopy in infants and children from birth to twelve years of age. The light carrier is also outside the lumen and does not obstruct the view. The light is focused on the larynx and gives a view equal to a speculum of much greater diameter. The long slanting end of the speculum contributes largely in producing this ocular appearance.

NEW TONSIL FORCEPS.

By ISIDOR F. SHAPIRO, M. D.,
New York.

The securing of a good grasp on the tonsil is, of course, essential to a successful dissection in the snaring method, particularly if the tonsil is of soft and friable consistency. The forceps illustrated has been found to have especially good seizing and holding qualities, due to the two new features of the

fenestration at A, and the receptive hollow at B; and being narrow, it does not get in the way of uvula or pillars.

In using this forceps the ordinary procedure is followed. It has been found that routine attention to the following steps gives uniformly good re-

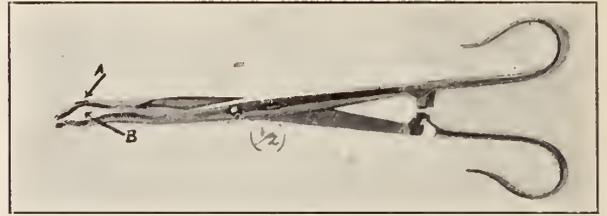

FIG. 1.—New tonsil forceps.

sults. First, using a tongue depressor, the forceps is inserted closed (to avoid grasping the uvula). Secondly, after the forceps touches the tonsil, its jaws are widely opened up to enclose both its lower and its upper poles. Third, before biting into the tissue the forceps is made to press the tonsil forward and outward, causing the anterior pillar to bulge. Fourth, in that position the jaws of the forceps are then shut, biting into the capsule. The operator may then proceed with his dissection, in the assurance that his forceps will not come away with small chunks of tonsil tissue.

For the subsequent dissection the author prefers an instrument which has the dissector combined on the other end of a tongue depressor (1). This enables the operator to save time in handling separate instruments, and before hemorrhage or frothy mucus has time to obscure the field he can complete the dissection and snaring, thus minimizing sponging and exposure of the patient to etherization.

355 EAST 149TH STREET.

Treatment of Stenosis of the Esophagus.—Nathan W. Green (*Annals of Surgery* June, 1921) gives the following résumé: There were eight cases; two were in adults and six were in children three years old and under. One case of stenosis in an adult was due to sulphuric acid, and the other was recurrent after being treated in childhood. One was without history of burn, and was unquestionably congenital. It was coupled with stenosis of the outlet of the stomach. One in an infant gave the history of coming on after diphtheria. All eight were improved. All but one were cured with the necessity of occasional bouginage. One required further slight dilatation by the oral route. Four had the string sawing operation of Abbe. These were the worst cases and have done very well. Four had dilatation through the esophagoscope and were not treated so vigorously. The results are as good, but all kept track of are dependent upon following up with the bougie. The longest interval in the last six cases in which the bougie has not been passed is a year. In the milder types of stricture dilatation through the esophagoscope is sufficient.

*Presented at the annual meeting of the Association of American Peroral Endoscopists, Boston, Mass., June 1, 1921.

Dangers to Life of Severe Involvement of the Thorax in Rickets.—Edwards A. Park and John Howland (*Bulletin of the Johns Hopkins Hospital*, April, 1921) based their study on thirty-two colored children, between the ages of eight months and four and a half years. All of them showed well marked rachitic deformities of the thorax, with great weakening of the thoracic wall, and all were greatly underweight and undersized. In all there were characteristic x ray findings in the chest, which are fully described. The authors state that deformity and normal thoracic function are compatible, so that the element of danger is not the deformity, but the loss of rigidity of the thoracic wall. The only course of treatment recommended is the administration of cod liver oil in moderate doses, and the avoidance of infection and of those things which give rise to abdominal distention.

Antiscorbutic Potency of Milk Powders.—E. B. Hart, H. Steenbock and N. R. Ellis (*Journal of Biological Chemistry*, April, 1921) using the guinea-pig as the experimental animal, fed it a basal ration of heated alfalfa flour, rolled oats, and common salt, to which was added the milk powder to be studied. Milk powder made by the Merrell-Soule or spray process, that developed at the California Central Creameries, and that made by the Just process were compared as to their antiscorbutic power. This was found to vary considerably, for aside from the initial quantity of the vitamine in the milk as influenced by feed, the method of manufacture was important as the Just process was less destructive of the antiscorbutic vitamine than the spray processes. The authors state, however, that milk powders made in this way should not be condemned, but that the results obtained demonstrate their limitations when used as the sole source of nutrients in infant feeding. Probably with all milk powders, irrespective of their method of manufacture, the safest plan in a restricted dietary, especially in infant feeding, is to supplement the diet with some potent source of antiscorbutic vitamine.

Stability of the Antiscorbutic Vitamine and Its Behavior to Various Treatments.—N. R. Ellis, H. Steenbock, and E. B. Hart (*Journal of Biological Chemistry*, April, 1921) deal in this paper with the properties of the antiscorbutic vitamine, its destructibility by various processes, and its behavior to some common reagents and solvents. Cabbage, both in the undried state and as sauerkraut, and corn in the form of silage, were studied, and the effect of various treatments on orange juice was described. The antiscorbutic vitamine was not removed from the latter by either ether or aeration. Such oxidizing agents as hydrogen peroxide and potassium permanganate destroyed it, but the mild reducing action of molecular hydrogen was without effect, and a measurable amount of the vitamine was removed by blood charcoal and the Chamberlain filter. Desiccation of cabbage in an atmosphere of carbon dioxide for thirty-five hours at 65° C. did not prevent the destruction of the antiscorbutic vitamine, but fermentation processes involved in the making of sauerkraut from cabbage and silage from corn resulted in its destruction.

Nutritive Properties of Milk.—H. A. Mattill and Ruth E. Conklin (*Journal of Biological Chemistry*, October, 1920) found in an experimental study in the albino rat that a ration containing dry milk and one per cent. of yeast was the only milk diet studied which would permit normal growth and partially successful reproduction, and the growth of rats on this ration and on one containing five per cent. of yeast has been practically normal.

Vitamines in Milk.—M. J. Rosenau (*Boston Medical and Surgical Journal*, May 5, 1921) states that canned milks and dried milks retain the fat soluble A and water soluble B vitamins in almost their original potency. The only vitamine in these preparations that may be affected is the antiscorbutic vitamine. The amount of this in canned milk will vary with many factors, primarily the amount in the original milk, and, secondarily, upon the process of heating and evaporation, with special reference to oxidation.

Surgical Complications of Influenza in Children.—Blanc y Fortacin (*La Medicina Ibera*, December 27, 1919) found that in the recent epidemic these complications took various forms, namely, peritoneal, pleuropulmonary, perinephritic and osteomyelitic. When influenza attacked surgical cases postoperatively the results were much more grave than when a surgical condition supervened upon an original grippal infection.

Clinical Indications for Tonsillectomy.—M. Quackenbos (*Medical Record*, April, 1920) sets down the following four local conditions indicating enucleation: 1, New growth; 2, incomplete tonsil operations previously done; 3, recurring acute inflammations; 4, hypertrophy associated with Eustachian or nasal obstruction, and a fifth may be added in diphtheria carriers. Three reflex conditions warrant enucleation: 1, cough due to an enlarged lingual tag; 2, nocturnal enuresis; 3, petitemal or meningism. Other indications are cervical adenitis, arthritis or joint lesions, middle ear deafness and acquired palsy in childhood. Waugh's method is that of election.

X Ray Pictures of the Bones in the Diagnosis of Syphilis in the Fetus and in Young Adults.—P. G. Shipley, J. W. Pearson, A. A. Weech, and C. H. Greene (*Bulletin of the Johns Hopkins Hospital*, March, 1921) recommend routine examination of the osseous system in newly born children as a source of valuable diagnostic data. They state that it will insure recognition of the presence of a hereditary infection in a certain number of children who otherwise might go unaided for some time before some clinical symptom of the accidental discovery of a positive Wassermann would secure for them the much needed treatment. Three hundred white fetuses formed the basis of this study, ranging in age from the sixth month of intrauterine life to nearly term. The skeletons of twenty-five per cent. of the first one hundred examined showed marked signs of lues, and forty-six of the first one hundred examined showed well marked or suspicious lesions. Lues of the fetus and newly born child apparently interferes very little, if at all, even in advanced cases, with skeletal growth.

Proceedings of Societies

BRITISH ROYAL SANITARY INSTITUTE.

*Thirty-second Congress and Health Exhibition,
Held in Folkestone, June 20 to 25, 1921.*

Alcohol and Alcoholism.—An interesting feature of this congress was a breakfast given by the National Temperance League, over which Viscount Burnham presided. Dr. Courtenay Weeks delivered an address in which he said that alcohol and alcoholism were great coefficients in damaged life and disease met with in the national life of Great Britain. On this point there was the evidence of the chief medical officer of the Board of Education who said that there were in Great Britain over a million children of school age so defective, mentally or physically, that they were unable to derive reasonable benefit from the educational facilities provided by the State. There was also the testimony of the national insurance commissioners who said that there were lost annually, through sickness and disability among insured people, the equivalent of fourteen million weeks' work. The army authorities, in the last year of the war, found that 64 per cent. of all the men examined were physically unfit for the work of a soldier. In the asylums there were 125,000 lunatics and 150,000 feeble-minded persons and the chief medical officer of the Ministry of Health said that if the deficiency was to be met, the first thing they had to deal with was alcohol.

Sir GEORGE NEWMAN, who was a real leader among men, had said that if England was to be a healthy nation alcohol must first be dealt with, then venereal diseases, and finally feeble-mindedness, but the three went hand in hand. During the war the liquor control board was set up in the interests of efficiency and many of the restrictions established by this board should be maintained in peace. Experts of the board had reported on the scientific position of alcohol. That report had been embodied in a syllabus on the hygiene of food and drink which he hoped members of the institute would do all in their power to have placed in the curricula of the schools of the country.

Industrial Hygiene.—Viscount BURNHAM, president of the section of industrial hygiene, in his presidential address, said that Great Britain had paid in full measure the penalty of her past greatness. She was the first country to be industrialized and in advocating new methods, perhaps still more in inculcating a new spirit, they had run counter of settled habits of old established industry. On the other hand, he said, if her industrial system was old, if not senile, they could not get rid of their own responsibilities by blaming those who had gone before them. In the Victorian era it would have been considered an interference with divine providence, as well as with individual liberty, to attempt anything in the direction of industrial hygiene. The Manchester School of Economists would have thought this mollicoddling. It

was not want of humanity but difference in point of view that caused them to adopt this policy. On the other hand, possibly they were going too far in the other direction and safeguards were certainly required to prevent the national character from becoming enervated and even emasculated by too much supervision and interference. In America, welfare work, if imposed by those in authority in the factories and mills, was resented as being paternalism, and it was essential that in connection with the work being done in industrial hygiene in Great Britain, there should not be the spirit of paternalism, but the spirit of copartnership. Unless there was a concordat between employer and employee, it would be found that the great difficulty lay in a veiled hostility or an indifference to their own welfare by the working class. It was essential that there should be a free and frank alliance between employers and employed. Unless there was cooperation of energy and good will, the progress of social science would be slow. In the Whitley councils we had machinery which was admirably adapted to embody the spirit and perform the duties involved in industrial health and welfare. Those councils were never meant to be arbitration boards to deal with wages alone, but unless we had the active assistance and cooperation of the working people employed in all national industries, no matter what the code of sanitary legislation, or the zeal of medical officers of health, or how great the sympathy and good intention of employers, they would effect nothing morally, and little in any sense, to reach the purpose in view. In conclusion, Viscount Burnham spoke of the conditions peculiar to the printing trade and the methods taken through sanitation and ventilation to stamp out printers's phthisis.

The Organization of Welfare Schemes.—A paper on this subject was read by Mr. ROBERT R. HYDE, director of the Industrial Welfare Society. In a discussion of the subject which followed, Sir ARTHUR NEWSHOLME said that in the United States very little was being done regarding factory hygiene from the governmental side. What was done was voluntary work by great industrial concerns where they realized that they were dependent upon the health and efficiency of the workers. In Great Britain there was some danger of welfare workers being regarded as a charitable institution, conferring benefits on the working classes. It was necessary to get rid of this idea entirely, as it was in the interests of the employer as much as the employed that the workers should do their work.

Mr. BARRON, a miner from Durham, said the one thing needed in the collieries at the present time was something that would relieve the suspicion existing between employers and employed. The truest economy was not the question of giving or receiving wages, but something that would make a man feel that he was more than a machine.

Sanitary Science and Preventive Medicine.—Sir LESLIE MACKENZIE, president of the section in Sanitary Science and Preventive Medicine, in his presidential address said that the new objective in preventive medicine was to produce fitness. This was one of the primary lessons of the war. If the signs of the times could be read, even in part, they seemed to indicate that in the coming years the races that constitute Great Britain would have to set themselves consciously and openly under the guidance of the best science, not merely to control great infections and otherwise to prepare a healthy environment, but also to equip each individual with the strength to produce and courage to endure. If we expected to maintain our pace in production, we must be quite clear that the duties of civilized living, if not so urgent apparently as the duties of war, were in the long run just as exacting and required for their performance the same high qualities of mind and body.

No more illuminating study in the whole range of public health was made during the war than the special investigation on industrial fatigue, bringing out just how the hours of labor, kind of food, character of work and general working conditions showed themselves in the form of increased or diminished output. During the past thirty years the drift had been from the study of environment to the study of individuals, and in medicine generally the drift had been from the study of end products to the incipient physiological deviations that need never become pathological. There was a dawning hope that in the years immediately before us the general public would have the benefit of the highest medical skill, informed by the latest medical science, by means of the improved organization of the whole forces of research and treatment.

Smoke Abatement.—PROFESSOR LEONARD HILL said that while coal fires were the cheapest source of radiant energy in luminous form required in our climate, the time spent in attending to it and the ill effects on health of smoke pollution made it the dearest.

Dr. J. S. OWENS, in an analysis of a London fog, said that to produce a dense smoke fog about four milligrams of soot to the cubic metre of air was all that was required. One milligram produced the ordinary winter haze. If a dense smoke extended over the whole of London and up to a height of four hundred feet, a trifle under two hundred tons of soot would be present. The domestic fires of London from six in the morning till nine at night produced over two hundred tons of soot, sufficient to produce one of the densest fogs.

The Effects of Environment on Output.—Dr. D. R. WILSON, secretary of the Industrial Fatigue Research Board, presented a summary of the results of the investigations made by the board of the effects of environment on output. In heavy work involving exposure to high temperatures, production, he said, underwent a persistent seasonal variation, being, with few exceptions, greater in winter than in summer. The opposite effect was suggested in light work, such as silk weaving. Good ventilation was found to neutralize seasonal

variations and was reflected in the evenness of output throughout the year. In silk weaving it was estimated that even good artificial light caused a reduction in output of ten per cent. compared with daylight.

Miners' Nystagmus.—Dr. D. LECHMERE ANDERSON presented a resolution, which was passed, that the home office should be urged to fix a standard refraction test for coal miners, with the object of diminishing the incidence of miners' nystagmus. It was possible, he said, to detect the primary symptoms of the disease in nearly twenty-five per cent. of the men engaged in the coal mines.

Personal and Domestic Hygiene.—The Mayoress of Folkestone presided at the meeting of the section devoted to a consideration of personal and domestic hygiene. In the course of her address she said that she had had many opportunities of seeing the necessity of increased cleanliness, both of the person and the home. She regretted, however, that the right people did not use the facilities at their disposal for personal cleanliness. With the provision of cheap public baths and of baths provided for in all the new housing schemes, personal cleanliness should not be a difficult matter. In the poorer houses, however, there was still a great lack of cleanliness, which was no doubt due to ignorance or laxity on the part of the mother. Much was being done in the schools today to teach the girls housewifery, cooking, and laundry work. This should have a beneficial effect. Much more might be done by the church agencies to bring obscure cases to the attention of the sanitary authorities, so that such persons might be visited and treated in the cleansing stations which all up to date authorities provided. She said that domestic hygiene was, to her mind, not a scientific subject, but might be summed up in one word—cleanliness. The later Sir Benjamin Ward once said that if by some magic spell England could wake up clean she would wake up pure in spirit and godly in the comprehension of godliness.

A general discussion on the hygiene of the home followed the reading of the main papers in this section. Dr. P. Jones, of Glamorgan, urged that the basis of public health in the future lay more in the direction of giving the people proper food than in providing nice houses to live in.

Dr. C. S. THOMPSON, of Hythe, suggested that in teaching children hygiene appeal should be made to their vanity. If a young girl was told that if she grew up with yellow teeth she would never get a husband she would begin at once to clean her teeth. He also said that the old idea that an expectant mother should be fed on stout in order that she would have plenty of milk should be suppressed.

Mrs. EVA FULLER, a member of the Dover town council, said she was of the working class and resented any suggestion that the working classes did not make the best use of their opportunities.

The Hospital as a Health Centre.—Mr. E. L. MARTYN LOBB read a paper dealing with the hospital as the primary health centre in relation to health service. He said that a health service should work for and secure the health of high and low,

rich and poor. More than that, health service must work to maintain health rather than to cure disease. "Public Health Is Purchasable," was the motto of the New York Health Department, he said. Given unlimited finance, an adequate health service would be a comparatively easy affair, but finance today was anything but unlimited. It would seem that the great renaissance of medicine which we were witnessing could hardly have occurred at a more inopportune moment. The hospitals said that they would not bear their present burdens, still less add to them, and municipal authorities, the public, and the ratepayers, while applauding the abstract idea of primary health centers dismissed it as a fantastic mirage, crying "not a penny from us." Medical practitioners viewed the scheme as an insidious attempt of socialistic dreamers to rob them of the little they might yet earn. It was certain that for many years to come we could not afford a perfect health service, but we could make a start with the facilities we had. As for hospitals, he maintained that better organization would relieve much of the pressure of crowded premises and long waiting lists. He hoped that the day of a sliding scale of payment by patients to a hospital was not far distant. Another abuse was that too many treatments were being given in hospitals which could just as well be carried out in the patient's home or in a convalescent home. It was time that a sort of doomsday book of England's convalescent accommodation was compiled and to every hospital, according to its size, a fraction of the available convalescent bed accommodation should be assured. Poor law infirmaries were empty to a large extent, and if the stigma of pauperism was removed from the name their doors might be thrown open to the hospitals for the accommodation of convalescent patients.

During the debate which followed, Doctor WHEATLEY, medical officer of health, for Shropshire, said he looked forward to a district nursing service trained in public health as a means of having many cases now treated in hospitals dealt with at home.

Doctor HANDFORD, of Nottingham, urged that hospitals must have more financial help from the insurance societies, a help to which they were morally entitled.

Mrs. PALMER, of Southampton, thought a State medical service was bound to come and the best organizations to control that service would be the already established health committees. Hospitals should concern themselves more with the prevention of disease and become centres of good health instead of centres of bad health and disease, as they were today. It was deplorable the number of medical men who failed to keep abreast of modern developments, and there should be research departments in connection with hospitals in which every medical man should be compelled to do a period of service. Although surgery had made great advances in recent years, medicine had made practically none.

Mr. ARTHUR F. WICKENDEN condemned the disregard of common sense principles in crowding

small houses with superfluous furniture and dust collecting bric-à-brac. When one took stock of the accumulation of pictures plastered over every available inch of wall space, one could solve for all time the problem of where the flies go in the winter time.

Miss AMY HUGHES said that there was need of a much wider education for parents. It was curious how many people accepted disease and ill health as inevitable and did not realize that a great deal of trouble could be avoided by following the rules of personal hygiene.

Letters to the Editors.

LITERATURE ON RESECTION OF THE TARSUS.

9 EAST FORTY-SIXTH STREET,
NEW YORK, June 17, 1921.

To the Editors:

I am in receipt of a reprint by Dr. Arthur S. Tenner, entitled Resection of the Tarsus and Conjunctiva, printed on March 16, 1921. This is the reprint of a paper read by the author before the Section in Ophthalmology of the New York Academy of Medicine, November 16, 1920, and published in your issue for March 16, 1921. I was present on the occasion of the reading of that paper.

In the references to the literature on the subject the author of the reprint and the reader of the paper on that occasion refers to H. W. Wootton and Hiwatari Kazuo alone. In the *Archives of Ophthalmology*, 1912, Vol. 41, p. 141, will be found an article by myself on the Resection of the Tarsus and Conjunctiva, with description of a clamp, whereby this operation can be performed practically in a bloodless manner. A cut of this clamp which I constructed, together with other illustrations showing the various steps of the operation as suggested by myself, can be found in that article. If one cares to refer to the paper by Dr. Tenner, he will observe that the cut of his clamp bears a striking resemblance to that which I invented, the difference consisting mainly in the presence of two spikes on Dr. Tenner's clamp and five on my own; likewise, he has at the end of his clamp a screw whereby the bar holding the spikes may be slid up and down.

Subsequent to the publication of a description of my instrument, a few months afterwards, Miss Ehrhart, a nurse at the New York Eye and Ear Hospital, had constructed a clamp, of which the one described by Tenner is almost an exact counterpart. Instead of the serrated teeth used by Miss Ehrhart, Tenner substituted the two spikes and in addition the aforementioned screw at the end of the instrument. To this Dr. Tenner makes no reference either in the paper as he read it or as it was printed in your journal. A description of Miss Ehrhart's instrument has not been published, I understand, but it is well known and has been used continually at the Eye and Ear Infirmary in resection of the tarsus.

A great deal depends on the matter of placing the sutures in this operation. I changed the method employed by Wootton in inserting the sutures, and

in my fourth conclusion stated as follows: "The line of the sutures is not at right angles to but is parallel to the border of the lid." Fig. 5 in my article will show this, and if the reader will refer to Fig. 3 in the article by Dr. Tenner, he will see that the stitches in the two cases are exactly alike. This may appear to be an insignificant matter, but it is not. Parallel sutures secure smoothness and complete adaptation of the conjunctiva to its new position in the lid, thereby preventing puckering.

It is usual, ethical, and proper, when one prepares a paper on a scientific subject, to acquaint himself with the literature bearing upon it, and all matters touching it. When questioned at the meeting before the section, Dr. Tenner disclaimed knowledge of these two instruments and said he was not well acquainted with my paper. My instrument was the first clamp invented for the performance of this operation. Any modification of that clamp or my procedures by anybody should have been attended by a reference to my paper and to the instruments constructed by myself and by Miss Ehrhart. Dr. Tenner disclaimed any intention, when the facts had been presented to him, of being disregarding of the proprieties or of taking credit from any one, nevertheless, in the publication in your journal, there is no footnote or postscript in support of his disclaimer.

It is unnecessary before ethical men to dilate upon the proprieties in such manners, but it is just, right, proper and imperative, that credit should be given where it is due, and that no one should take the ideas or appropriate the efforts of others in exploiting his own endeavors. If all men insist strictly on the enforcement of such principles, much confusion will be avoided and subsequent generations will not be confounded by different claimants to priority. Witness in this connection, the contention in regard to the introduction of ether in the practice of medicine as an anesthetic.

The Scripture has said that ignorance is no excuse, the assumption being that the means of information are at hand. Dr. Tenner refers to the paper of Dr. Wootton in the *Archives of Ophthalmology* in 1910. My paper was published in the *Archives of Ophthalmology* in March, 1912. Dr. Tenner evidently had the means of information at hand.

J. H. CLAIBORNE, M. D.

CHICAGO, June 9, 1921.

To the Editors:

Dr. A. S. Tenner's favorable report of Tarsus Resection in Trachoma published in the *NEW YORK MEDICAL JOURNAL* for March 16, 1921, seems hardly to represent correctly its status in the United States and Egypt. He asserts that "the American literature on the subject is exceedingly scanty" and refers to "Wootton's classical paper (1910)" as if it were the first to be published in this country. In justice to my colleague, Dr. Casey Wood, now in Europe, I feel compelled to remind Dr. Tenner and others that not only were the Heisrath procedure and all its modifications carefully described, thoroughly discussed, and well illustrated, but a voluminous literature on the subject appeared many

years before the appearance of Wootton's paper in 1910.

It is well known that Dr. Wood was the first one to introduce this subject to English readers and he has in several journals and before a number of societies asserted its extreme value in certain forms of trachoma, reporting numerous instances of relief in intractable cases, with accompanying histories, illustrations of instruments, and description of technic. His earliest paper was published in 1898 in the *Annals of Ophthalmology* (page 372); another in the *American Journal of Ophthalmology* in July, 1903; still another in the *Practical Medicine Series* for 1913. Finally, the whole matter is fully thrashed out (including an abstract of Dr. Wootton's "classical paper (1910)" in the *American Encyclopedia of Ophthalmology* under the caption Trachoma.

Dr. Tenner should also read Dr. A. F. MacCallan's (Cairo) approval of this method, published some years ago and mentioned also by Dr. Wood in his well known report of two trips to Egypt appearing in the *Ophthalmic Record*.

After all, nothing really worth while has been added to the experience and observations of Jacobson, Heisrath, and Kuhnt in this matter. It was, as Dr. Wood clearly pointed out, chiefly to the last named that we are indebted for the improvements in a measure that the two former observers were instrumental in giving to the surgical world.

FRANK ALLPORT, M.D.

A MANUFACTURER'S PROTEST.

CINCINNATI, OHIO, July 28, 1921.

To the Editors:

Our attention has been called to statements appearing in a number of professional journals which might lead some physicians to believe we had discontinued the manufacture of proteogens. Such is emphatically not the case.

In order to keep up with the tremendous strides that are being made in biochemistry and to keep our nonspecific protein products, known under the registered trade name of proteogens, well in advance of other products, we have recently reorganized our biochemical laboratories.

As a result of this reorganization the name of Horovitz no longer appears on the labels and literature of our products. The present state of perfection of proteogens is due entirely to experimental work in our own laboratories, where under expert supervision these products are being further improved. The research work connected with the development of proteogens is now in charge of an American biochemist of unquestioned reputation and highest scientific standing.

We trust, therefore, that the pharmaceutical and medical professions will not be misled by any false claims. The nonspecific vegetable protein solutions originally supplied in ampoules under the name of proteogens are manufactured by the Wm. S. Merrell Company. You are urged, therefore, to insist upon receiving original sealed packages bearing the name of this company and the registered word proteogens.

tation through the mail as second class matter.

NEW YORK, WEDNESDAY, AUGUST 17, 1921.

Miscellany.

Experiences of the Child.—C. Macfie Campbell (*Mental Hygiene*, April, 1920) states that it is time to eliminate the mystery attached to taboo. The child as he develops has of course to outgrow the more primitive reactions, subordinating them to the more mature and socially important reactions. The child can, however, be encouraged to outgrow primitive reactions without giving to them false values; he can learn frankly how more mature values supersede the less mature, but he can do this while still realizing that his native promptings and questionings are the real stuff out of which his life is to be made, and that they are all fit to be subjects of honest scrutiny and of trustworthy information.

Nonrheumatic Aortic Stenosis in Young Subjects.—Gallavardin (*Presse médicale*, March 19, 1921) refers to the occurrence, usually in young individuals, of a form of aortic stenosis with clear-cut physical signs which neither corresponds to what is now known of congenital aortic stenosis nor is of arterial nonrheumatic origin. As a rule, the stenosis is quite uncomplicated; where accompanied by slight regurgitation it always remains distinctly predominant. Clinically, this form of stenosis is well tolerated for a prolonged period; it may, however, in its advanced stages be associated with disturbances of function, and in some instances developmental disturbances have been reported. The origin of the disorder is in doubt. In a few cases, possibly, it consists in a congenital lesion which is revealed late; but in the majority of cases it appears rather to be an acquired lesion, developed slowly during childhood or adolescence on account of a subacute or chronic endocarditis, due to some as yet undetermined factor. The several features of this disorder warrant comparison of it with the mitral stenosis of Duroziez.

Manganese in Pediatric Therapeutics.—Camescasse (*Presse médicale*, March 19, 1921) refers to certain children who, in spite of having been kept for a time in the country, remained subnormal in body weight. The weight showed a notable increase and the general condition improved upon administration of manganese dioxide in a daily dose of 0.03 to 0.07 gram.

Destruction of Fleas.—Loir and Legangneux (*Journal de médecine de Bordeaux*, March 10, 1921) recommend the solution of 300 grams of soap in 1500 grams of water, followed by the addition of eight litres of coal oil. An emulsion is made by shaking the mixture. Just before use, one part of this emulsion is poured into twenty parts of water. The resulting mixture is applied over the woodwork and poured between the cracks in the flooring. For protection of the person against flea bites oil of cloves and tincture of cevadilla are serviceable.

Studies on Measles.—Francis G. Blake and James D. Trask (*Journal of Experimental Medicine*, May, 1921) describe a series of reinoculation experiments in monkeys which had recovered from a previous attack of experimental measles. It was found that one attack of experimental measles apparently conferred a complete immunity against reinfection for at least a considerable period, and in all probability, permanently. This was true whether the virus of measles was of homologous or heterologous origin. In this respect experimental measles in the monkey corresponds with measles observed in human beings.

Syphilitic and Familial Graves's Disease.—Leredde and Drouet (*Presse médicale*, March 16, 1921) refer to the case of a woman in whom exophthalmic goitre set in during the war after she had been greatly alarmed by an airplane raid. Three other cases of Graves's disease are known and three more believed to exist in the same family. In the four cases actually under observation the Wassermann reaction was negative, but the Hecht reaction, tested in the first patient, was positive at first and later became negative under treatment. The tachycardia and palpitations disappeared under novarsenobenzol therapy, but lumbar puncture yielded a still positive Wassermann reaction in the cerebrospinal fluid. The case is thus believed to be one of syphilitic exophthalmic goitre due to syphilis in the second generation.

Complement Fixation Test in Tuberculosis.—A. L. Punch (*Lancet*, September 25, 1920), basing his studies on the work of Wassermann and Bruch, has investigated the complement fixation abilities of the blood of tuberculous patients, with the view of finding a definite test for the presence of tuberculous lesions. He uses an emulsion of tubercle bacilli as antigen, in three dilutions. The author concludes that: 1. The complement fixation test specifically indicates the presence or absence of an active or recently active lesion. 2. A positive reaction in the highest dilution of the complement used is as reliable an indication as positive reactions in the other dilutions. He believes that positive reactions in the case of arrested tuberculosis are due to the persistence of antibodies in the blood.

Peritonitis*

By JOHN B. DEEVER, M. D.,
Philadelphia.

I am not aware that I can offer anything new on the subject of peritonitis, but I believe that it is one of such vast importance that it does not suffer from being repeated from time to time, even though its most salient features are probably familiar to us all. I will not discuss the microscopic anatomy of the peritoneum as to the presence or absence of stomata, nor will I discuss whether the peritoneum is a part of the lymphatic system or not; this is really only of academic importance. What we want to know is that the peritoneum has great absorptive and exudative power.

THE PERITONEUM.

The peritoneum, by its folds, convolutions and fossæ, is without doubt the most extensive serous membrane of the human body, covering as it does an area almost equal to that of the skin. It is a complex sac containing several diverticula and the hollow and solid viscera, the latter projecting into the cavity but being shut out of the cavity proper by their serous covering of peritoneum, the visceral layer. Its function is mainly protective, in that it provides a surface which permits free play upon each of the other organs which it covers, the proper degree of lubrication being maintained by its remarkable powers of exudation and absorption, the chief characteristic of the peritoneum. One of the most important factors in peritoneal absorption is the vitality of its endothelium represented by a single continuous layer of delicate, flat, endothelial cells, by virtue of which the peritoneum remains a cavity in spite of its folds and undulations. Normally the equilibrium between exudation and absorption is so well balanced that there is never an excess of fluid in the peritoneal cavity, therefore the presence of even a small amount of free fluid must be taken as an indication of the presence of some pathological process. It is also owing to these same phenomena that protective temporary adhesions are formed in the peritoneum by which its surfaces adhere to each other when irritated by a reactive process, and which leads to the familiar walling off of the affected area that prevents the diffusion of the infection, for peritonitis is always due

to bacterial infection. Aside from the very rare cases of so-called chemical and idiopathic peritonitis, which probably represent a hematogenous or lymphatic infection, the most important source of infection in peritonitis is directly from some intraabdominal organ, mainly the appendix, the intestines, the female internal genital organs, the stomach, and the gallbladder, the result either of trauma or disease or both.

TYPES OF PERITONITIS.

The question of chemical and mechanical peritonitis is one around which considerable discussion has always centred. The term chemical peritonitis, according to Murphy, is a convenient one for those instances in which typical peritonitis is produced by the introduction of presumably sterile substances into the cavity, such as the contents of a ruptured ovarian cyst, or some chemical, either foreign or coming from adjacent viscera. At bottom, however, I am inclined to believe that this form of peritonitis is infective, inasmuch as the excoriation of the endothelium prepares the way for the entrance of pathogenic bacteria, in the same way as the twisting of a pedicle of a tumor, the presence of a foreign body, such as a sponge, with the resulting reddening and exudation, represent what may be termed a mechanical peritonitis by preparing the way for the bacteria to gain a foothold in the peritoneum.

The first effect of the bacterial invasion is a hyperemia with exudation into the subperitoneal tissue of the part around the infected focus, soon followed by exudation of fluid into the peritoneal cavity. This fluid is at first protective and bactericidal in character, but by impairment of its vitality it is gradually converted into pus, the rate of the conversion being dependent upon the degree of intraabdominal tension, the virulence of the infecting organism and the individual power of resistance.

It is well known that the presence of practically any foreign substance is capable of producing irritation in the peritoneal cavity. Blood, bile, and urine, even if not infected, will excite an inflammatory reaction, the two last named being especially irritating; when present they interfere with intestinal function and damage the walls of the intestine and thus favor bacterial invasion of the peritoneal

*Read before the Philadelphia County Medical Society, March 9, 1921.

cavity. In the presence of a perforating viscus the bile and urine may already be infected and their extravasation into the peritoneal cavity will set up an infective and irritative peritonitis. Such double peritonitides result, for example, from perforations of the stomach, duodenum and gallbladder in which bile and activated pancreatic secretion play a part. Peritonitis from the lower intestinal tract and the female pelvis is also infective and bacterial in nature.

EXUDATION AND ABSORPTION.

Whatever the source of the irritation or the inflammation, the result is abnormal activity of the phenomena of exudation and disturbance of the rate of absorption. From the results of extensive and careful experimental work we know that absorption takes place through the lymphatics or through the blood stream and in this way bacteria and their products are distributed to the lymphatic tract and the circulation, while at the same time there is an excess of serous exudation in the peritoneum. Absorption takes place through the lymphatics and the bloodvessels, both fluid and soluble substances being absorbed by both sets of vessels, while acid substances (bacteria, foreign, animal cells) are absorbed almost, if not quite, exclusively through the lymphatics. Absorption by the blood stream constitutes one of the greatest perils of peritonitis. On account of the wonderful absorptive power of the peritoneum it makes its own toilet. Early in the process, unless the exciting organism is one of great virulence, the resistance of the body and particularly the protective powers of lymph and of phagocytic leucocytes assist in inducing more or less prompt absorption. But the protective properties of this early turbid peritoneum fluid are lost soon after the serous and seropurulent stages of exudation are passed, and the damaged peritoneal membrane responds by depositing a fibrinous material rich in leucocytes, and thick and tenacious. The effects of this deposit is cofferdamming the lymph and bloodvessels and cementing the adjacent peritoneal structures together, thus shutting off and isolating areas which are so highly infected as to interfere with absorption and the bacterial action of the exuded fluid.

The infective process may go on within this walled off area, while the general cavity remains protected against its spread. It stands to reason, therefore, that the essential feature in the treatment of peritonitis is not to interfere with the walling off or localization process and to avoid any measures that favor its diffusion. Murphy, in his classical paper on peritonitis, aptly compared the rôle of fibrin in the peritoneal cavity to the action of a board of health in protecting a community by isolating infected individuals.

Diffusion, we know, is increased by general bodily activity and movements of the diaphragm, and that reduced respiratory force and peristaltic movements are Nature's way of preventing diffusion. Practically we make use of this knowledge by putting the body at complete rest and by means of proper posture encouraging the gravitation of the noxious fluids to the lower and less dangerous portions of the peritoneal cavity. It is a well known

fact that peritonitis arising from lower areas of the peritoneal cavity are less serious than those coming from the upper zones, because the greater activity of absorption in the diaphragm in the upper portion favors diffusion. The rhythmic pumplike action of the diaphragm, in action day and night like the heart, is one of the most important factors in aiding peritoneal absorption, its alternating contraction and relaxation being instrumental in sending onward fluid and particles aspirated from the peritoneum. In addition to this, peristaltic activity is of equal importance in that it favors an even distribution of fluids and prevents their accumulation in the pelvis toward which they naturally gravitate.

QUESTION OF BACTERIAL FLORA.

As to the question of bacterial flora in peritonitis, it is today generally recognized that it nearly always is a mixed one, the most important organisms being the staphylococcus albus, colon bacillus, streptococcus, pneumococcus, typhoid bacillus and gonococcus.

Great stress is laid on the protective influence of the staphylococcus albus which, according to Dudgeon and Sargent, is the first to appear and the last to disappear in peritonitis of intestinal origin, and whose presence in conjunction with other organisms influences prognosis. In the presence of abundant phagocytes and staphylococci at a site distant from the focus of infection the prognosis is favorable; it is grave but not hopeless if some bacilli are associated with these organisms, and very grave if only a few phagocytes, few staphylococci and numerous bacilli or streptococci are present.

The importance of the colon bacillus is generally recognized, although the idea that every peritonitis of intestinal origin is due to this organism exclusively is not supported by facts. The error is probably due to the well known rapidity with which the colon bacillus increases and its tendency to overshadow the other associated organisms.

STREPTOCOCCIC PERITONITIS.

Streptococcic peritonitis occurs more frequently in women than in men because of the greater frequency of that organism in pelvic infections of the female. When due to pelvic inflammation, as in puerperal infections, this streptococcic inflammation is a retroperitoneal phenomenon, and is familiarly known as concealed erysipelas. A form of streptococcic infection of the peritoneum is occasionally reported in which the peritoneum becomes involved without concomitant involvement of any of the abdominal viscera. The route of infection in these instances is by way of the blood stream, the source being acute inflammation of the nasopharynx, particularly the tonsils. The relationship of this type of peritonitis and streptococcic epidemic sore throat has been suggested by observations made during recent epidemics of this character. The cases observed show a tendency to affect females, especially among children, rather than males. Pneumococcic peritonitis is not common, although cases are being reported with increasing frequency. It is a fatal form of infection, and occurs more often among female children than among adults.

Sometimes pneumococcic peritonitis arises secondarily to pneumonia. According to Hertzler, this

occurs in one per cent. or less of all pneumonias, and it also affects little girls more often than boys and children more frequently than adults, the sex incidence of the latter being about equal. Gonococcic infective peritonitis is probably the most clearly defined type of inflammation originating as it generally does from an infected Fallopian tube and being marked by sudden stormy onset and early localization in the lower abdominal cavity, usually at one side.

PERFORATION.

By far the most frequent avenue by which the peritoneum becomes infected is from perforation of some intraabdominal viscus—the most common, of course, being the appendix. But, whatever its origin, the symptoms of peritonitis have much in common. In the order of their occurrence these symptoms comprise pain, vomiting, fever, distention, and rigidity. The pain, especially in the presence of perforation, is sudden and severe, its intensity varying somewhat according to the organ involved and its pathological condition.

SYMPTOMS.

In appendicitis, for example, the most common source of peritonitis, the initial pain is very severe, owing to occlusion of the appendicular artery and beginning necrosis, but later, when necrosis is complete, the pain loses its severity, indeed it may subside altogether. This subsidence without doubt is the most serious of the many insidious features of nearly all types of peritonitis, more particularly, however, of appendicitis. The false security aroused is responsible for many of the fatal cases of acute appendicitis.

The initial pain is often accompanied by a chilly sensation or a distinct chill, and in case of perforation is soon followed by primary reflex nausea and vomiting and the typical reflex rigidity and exquisite tenderness of the abdominal muscles, the latter being usually more marked over the seat of the trouble; the picture of the patient, with thighs drawn up, shoulders high, and superficial and costal respiration, is too familiar to need more than passing mention. It evidences the fact that much of the pain is due to friction of one diseased part against the other, and represents an involuntary act of protection against such contact. The pulse is rapid, small, thin and wiry.

The temperature at first is low, especially in the presence of a large perforation, but it very soon rises to considerable height. The temperature, however, is not of much diagnostic or prognostic value. The vomiting is often interpreted as Nature's effort to throw off the toxins absorbed by the gastrointestinal tract. It is well to aid the process by the use, not of purgatives, but of gastric lavage. The abdomen usually becomes distended and tympanitic. In the fatal cases the patient shows all the distressing signs of general toxemia until relieved by death.

DANGER OF PURGATION.

The danger of purgation in acute abdominal conditions is one that cannot be too frequently emphasized. While it is true that the practice is on the wane among physicians, it nevertheless is still en-

tirely too common among the laity, and it is the manifest duty of a general body like the County Medical Society to spread effectual propaganda on this subject. About sixty per cent. of my cases of acute appendicitis at the Lankenau Hospital give a history of purgation, and of these about seventy-two per cent. are complicated by pus, abscess, gangrene or perforation, and in many instances a combination of these catastrophes.

There are, of course, some cases, fortunately few, in which the virulence of the infection is such that nothing that can be done is of avail, and at the other extreme there are mild cases in which the inflammation is transitory and will subside with or without treatment, with or without leaving any trace of its presence. But it is impossible to tell which of such cases will or will not subside, for so much depends on the degree, and the type of infection. While the peritoneum can take care of a moderate number of virulent organisms, their presence in numbers beyond the limit of tolerance may result in a dangerous peritonitis, and if eventually perforation and gangrene develop the disaster is complete.

LOCALIZATION OF INFECTION.

The localization of the infection is also important because, as is well known, infections of the pelvis, the lower abdomen, are less serious than those of the upper abdomen, and infection involving the margins of the peritoneal cavity are not so dangerous as when the infection is central and the coils of the small bowel are involved. The folds of the peritoneum and the mesenteries play a part in limiting the peritoneal inflammation and directing its spread. The most potent protective agent in this respect is the great omentum, which stands guard, and at the first sign of danger wraps itself around the inflamed areas and endeavors to protect them against slow perforation, shuts out purulent collection, and aids in absorption and exudation.

In the absence of injury to the endothelium, bacteria and foreign substances will, within limits, be safely disposed of by the lymphatic route, but danger to the endothelial cells permits absorption by the vascular route. The uninjured hands, for example, may be soaked in virulent material with comparative impunity, but if there are abrasions, epidermis being denuded, infection is almost sure to follow. Similarly, in the peritoneum, among the factors favoring absorption are abrasions or exfoliation of the endothelium, tearing of peritoneal adhesions, and consequent exposure of the underlying vessels.

If the picture of peritonitis as we know it was of the early stage of the disease the question of treatment would be much simplified; but the classical picture is that of the disease in a more or less advanced stage, and there enters the question of when to operate. Peritonitis is seen either as a circumscribed or diffused inflammation. The terms diffusing, general, universal, are nothing more than advanced stages of the diffused variety, therefore should not be used, as they only tend to confuse. In a diffuse appendiceal peritonitis, with no definite point of localization and with peristalsis absent, the question of operation was at one time a difficult matter. But with the recognition by Ochsner, Murphy, Fowler and their followers of the value of

complete rest and the institution of the now generally accepted treatment which bears their names, the question of when to operate is more easily decided.

TIME OF OPERATION.

There is, I am aware, a certain class of surgeons who boast of operating in every case of acute appendicitis no matter at what stage it may be. I have expressed my opinion of this procedure on numerous occasions, and will here repeat that he who operates in a case of acute diffusing peritonitis after the first thirty-six or forty-eight hours of the onset of the peritoneal inflammation with no evidence of a localizing point is, in the majority of cases, not serving the best interests of his patients, nor his own best interest either, nor that of the profession. Operation at an indiscreet time in the presence of diffused peritonitis and in the absence of a localizing point, liberates toxins which are the cause of death in these cases. Although occasionally a patient may get well in spite of precipitous and ill advised operation, the operative mortality in these cases is sure to be a high one. Success in this type of surgery, I cannot help thinking, is much a matter of luck—no matter how skilful the surgeon. Judgment is as indispensable to successful surgery as is skill.

In the presence of a circumscribed peritonitis with a localizing definite point of exquisite tenderness, due to an acutely inflamed, perforating or gangrenous appendix, operation can be undertaken, in the absence, of course, of constitutional or other contraindications, provided the proper technic is observed with respect to safeguarding the peritoneum from contamination by the proper disposition of gauze packings. After removal of the appendix, the operation can be completed by providing for drainage and closing the wound up to the point of exit of the drainage or by not closing the wound at all. In cases of abscess treated as open wounds which have already filled in, it is not my practice to suture. While this may and usually does lead to a subsequent hernia, I believe, nevertheless, that it is better to repair the deformity when the tissues have recovered their normal vitality.

SEVERE INFECTION.

In badly infected cases where the peritoneum in the immediate neighborhood of the lesion is green and there is foul smelling pus, the infected cavity should be surrounded by a rubber dam or oiled silk, and lightly packed with gauze; the wound is left open but silkworm gut should be carried through the margins of the wound and tied loosely to prevent protrusion of the intestines. The packing should be allowed to remain in for several days before being removed. If in addition to the cofferdamming, rubber drainage has been placed in the subhepatic space, or between the diaphragm and the liver, and a glass or rubber tube placed in the pelvis, the latter should be removed when aspiration yields a straw colored fluid. If, at the end of twenty-four hours, the glass or rubber tube contains pus, if glass it should be replaced by one of rubber carried down into the pelvis through the glass tube and the latter gently withdrawn by revolving it around the rubber tube; if rubber, it should be left in. At

the end of four to six days the rubber tube can be gradually withdrawn, cutting off the projecting end a little at a time until it is entirely removed. Before the cofferdam is removed it should be soaked several times daily with hypertonic salt solution and also during its removal. This policy is best to pursue in cases of peritonitis where the assumption is reasonable that the trouble has its origin in the appendix, or the lower abdomen; but where the symptoms indicate perforation of one of the larger viscera, such as the stomach or the duodenum, immediate operation is urgent. Peritonitis, the result of intestinal obstruction, gastric, duodenal, gallbladder, intestinal or colonic perforation, should be immediately operated upon if the condition can be recognized, which it usually can if the case is seen early. The longer the peritonitis exists, other things being equal, the more grave the outlook. Peritonitis is dangerous directly in proportion to absorption. It is not the inflammation of the peritoneum that is fatal, but the toxins which are absorbed from its products that cause the severe manifestations or perhaps death. It is true that severe peritonitis of several hours' duration often masks the situation so completely that differential diagnosis may be impossible. Nevertheless, a carefully taken history will generally be of the greatest aid. By far the vast majority of cases of perforating gastric or duodenal ulcer give a previous history of digestive disturbance, while if the gallbladder is at fault it is almost sure to have been preceded by indications of cholecystic disease, either calculous or noncalculous.

POSTOPERATIVE TREATMENT.

Postoperative treatment differs little from operative. Purgation here is as ill advised as before operation. The lower bowel can be emptied by a gently given enema. The upper bowel will take care of itself and will begin to empty as soon as nourishment is given, which can be done as soon as the passing of flatus indicates the subsidence of the storm, and peristalsis is restored. The quiescence of the intestine is a prime factor in bringing about early circumscription of the process by adhesions.

Too thorough operation in peritonitis very often spells death. Peritonitis is dangerous directly in proportion to the absorption. It is not the inflammation of the peritoneum that is fatal, but the toxins which are absorbed from the products of the inflammation that cause death. In cases where it is necessary to prolong the fasting period beyond forty-eight hours nourishment must be provided by means of nutrient enemas, according to the judgment of the individual surgeon or practitioner, that is, adding nutriment to the salt solution.

1634 WALNUT STREET.

Determination of the Acidity of Gastric Contents.—Alfred T. Shohl (*Bulletin of the Johns Hopkins Hospital*, May, 1920) states that in order to determine the acidity of gastric contents by methods based upon sound principles one must consider acidity in terms of ionization and hydrogen ion concentration. The expression of gastric acidity in terms of pH (hydrogen ion concentration) will bring out clearly the relation between acidity and peptic digestion.

Surgical Conditions of the Stomach*

By JOHN J. GILBRIDE, A. M., M. D.,
Philadelphia.

Ulcer and its complications are the most common surgical conditions of the stomach. The three outstanding essentials in the surgical treatment of gastric ulcer are, first, the selection of the cases for operation; second, the technic of the operation, and, third, the aftercare of the patient.

The treatment of acute peptic ulcer of the stomach belongs to the internist. In the first place, it goes without saying that one must be certain so far as possible that the diagnosis is correct. Many cases that were thought to be gastric ulcer proved on further investigation to be duodenal ulcer, cholelithiasis, or not infrequently chronic appendicitis. It has also been shown that gastric ulcer is not as common a disease as was formerly believed. In many cases one cannot make an absolutely positive diagnosis of peptic ulcer on the clinical findings alone, but these must be corroborated by the x ray or by operative findings. It has been stated that more mistakes have been made in the diagnosis of gastric ulcer than in any other abdominal disorder. Duodenal ulcer occurs two, three or four times as often as gastric ulcer; cholelithiasis occurs even more often than duodenal ulcer, differing in frequency according to different authors, and it is not an uncommon experience to see patients, whose symptoms and laboratory findings are suggestive of gastric ulcer, subsequently suffer from an acute attack of appendicitis which when followed by operation usually results in a complete cure of the gastric symptoms.

About ten per cent. of the cases of gastric ulcer are penetrating ulcers, usually into the liver, spleen, or other surrounding structures.

The first case of this type that I ever saw was in a cadaver, in which the ulcer was of the lesser curvature of the stomach, circular, craterlike, measuring about three inches and a half in diameter. The wall of the glass was formed by the under surface of the liver to which the stomach was strongly adherent. Eggleston says that penetrating ulcers are usually diagnosed only by the use of the x ray, but their presence may be suspected by certain clinically distinguishing features of pain of greater severity, greater local tenderness, and absence of relief from the administration of alkalis. When the stomach is empty and peristalsis is more or less at rest these patients may be quite free from pain or other symptoms suggestive of adhesions.

Repeated hemorrhage is a condition demanding surgical intervention and for its arrest a simple gastroenterostomy may be sufficient, but in some cases it is also necessary for one to deal locally with the ulcer in conjunction with the performance of a gastroenterostomy. In about twelve per cent. of the cases of gastric ulcer gross hemorrhage or macroscopic blood occurs. In over eight per cent. of

cases of gastric ulcer with a history of hemorrhage before operation, there is a history of hemorrhage following the operation. The best method of dealing with the ulcer is to excise it and then perform a gastroenterostomy. Hemorrhage has occurred after infolding of the ulcer. Hemorrhage in these cases may occur months or even years after the operation. In the selection of cases for operation the best results are obtained in those cases where medical treatment has been tried, but has failed to effect a cure.

Many cases of ulcer of the pylorus, in which there is a swelling producing a moderate grade of obstruction, yield promptly to medical treatment. I have found the Sippy treatment very satisfactory and cases that respond usually do so within a few days. As an illustration of the improvement which takes place in patients with pyloric ulcer and in those in whom the obstruction and the other symptoms were severe enough to demand operation after the performance of a gastroenterostomy the pylorus frequently becomes patent and functionates properly. In some cases the stoma formed at operation becomes nearly closed and in other cases the gastroenterostomy produces symptoms which demand restoration of the normal condition by taking down the gastroenterostomy. As stated, many cases respond in a few days to medical treatment, but if it is deemed advisable to continue medical treatment a few weeks should decide as to whether surgical intervention is required.

So far as rectal feeding is concerned, I think the theory was exploded years ago and it has been proved conclusively that nutrition cannot be maintained in this manner. Fluid is supplied to the body but that is all. The Einhorn tube is both serviceable and practical. May the starvation treatment never return. Chronic ulcer of the stomach which has been treated medically without success should be operated upon. As to the diagnosis of ulcer of the stomach, William J. Mayo says that the x ray gives a correct diagnosis in about seventy-one per cent. of the cases, and that clinical diagnosis is correct in about seventy-one per cent. of the cases.

It is difficult to determine the frequency with which gastric ulcer undergoes malignant degeneration. Wilensky and Thalheimer made serial sections of gastric ulcers that had been diagnosed benign after a single section had been examined and found many of these to be malignant. Aschoff points out that if the lesion is cancer originally the base of the ulcer will prove to be cancer, while Wilson and MacCarty have shown that in cancer on ulcer the cancer existed in the overhanging edge of the ulcer and not in the base.

A new symptomatology must be written for gastric carcinoma. The old one of vomiting of coffee ground blood, emaciation, cachexia, glandular enlargement, including the wrong notion about the age of after forty, will not do. The laboratory findings also are mostly the findings of long standing

*Part of an address delivered before the Lancaster County and City Medical Society, Lancaster, Pa., November 3, 1920, and before the York County Medical Society, York, Pa., March 3, 1921.

disease, namely, the presence of lactic acid, Oppler Boas bacilli, etc. When all these are present one can be certain that the diagnosis is malignancy, but that does not do the patient any good.

The same thing is true in the findings of gastric and duodenal ulcer. For I doubt if there is any surgeon who is at the present time influenced to any great extent by the presence or the absence of hydrochloric acid in the gastric contents. The only practical thing that we can see at the present time that will enable us to get cases of cancer of the stomach earlier is the early use of the x ray. The only treatment that offers any hope for the patient with cancer of the stomach is the removal of the growth and the invaded lymphatics, as gastroenterostomy is only a palliative procedure, good, of course, when one is unable to do anything better. There is one other point about the use of the x ray which I think is necessary, not only in cases of cancer of the stomach but in cancer of other organs as well, and that is, that other parts in which metastasis is likely to occur should also be included in the picture, as it would not be worth while to operate for the removal

of a malignant growth when metastasis has occurred. Patients with cancer of the stomach may be improved considerably by preoperative treatment for a few days or even longer by forced feeding with milk, raw eggs, thin gruels and possibly by the addition of small amounts of whiskey. Cancer of the pylorus rarely produces complete obstruction, therefore, a liquid food usually passes through the pylorus.

The treatment after the operation is also important, as these patients usually have been on a starvation diet, and sometimes either through lack of liquids or from vomiting the tissues have become dehydrated, which also affects other excretions and secretions. Feeding should, therefore, begin after the operation as soon as the stomach becomes retentive. If the stomach is not retentive gastric lavage should be resorted to until it is retentive. It is my practice to begin giving nourishment in the form of albumen water within twelve hours after the operation. The quantity of food is gradually increased according to toleration by the patient.

1934 CHESTNUT STREET.

The Action of Various Salts and Other Substances on the Liver After Their Introduction Into the Duodenum*

Second Series.

By MAX EINHORN, M. D.,
New York.

In a paper recently published (1) it was shown, as first stated by Lyon, that magnesium sulphate when injected into the duodenum, usually provoked a color reaction in the bile. The reaction in most instances takes place gradually, reaches an acme of color intensity (becoming very dark), then step by step diminishes, returning to a light yellow. The dark bile did not appear to be real gallbladder bile as Lyon assumed, for the following reasons:

1. If the color change of the bile was due to the action of the magnesium sulphate on the gallbladder causing an emptying of its contents, the change of color would necessarily be an abrupt one, beginning and ending sharply. This, however, is not ordinarily the case.

2. Magnesium sulphate, which is believed by Meltzer to relax Oddi's sphincter and by Lyon to cause the emptying of the gallbladder, would in this way have no direct effect on the character of the bile evacuated. Solutions of twenty-five per cent. or ten per cent. of magnesium sulphate would, if the emptying of the gallbladder is accomplished, furnish a bile of identical color and other qualities. This, however, is not the case, the stronger the magnesium sulphate solution, the darker the color and the higher the specific gravity of the bile, indicating that the magnesium sulphate has a direct influence on the bile itself.

3. A great many other salts (which have no relaxing action) like sodium sulphate, bicarbonate of soda, and other chemicals, act in a manner similar to that of magnesium sulphate, effecting the color reaction named above. The latter must be due to the action of these ingredients on the liver and the bile production, and not to a mere evacuation of the gallbladder contents.

4. After applying the magnesium sulphate test, an immediate repetition of the test frequently provokes a reiteration of the same reaction with its entire series of color plays. If the dark bile would be gallbladder bile, the reaction could not take place anew right after the gallbladder had emptied its contents.

5. Patients whose gallbladders have been removed frequently give similar reactions after magnesium sulphate instillation, clearly showing that the gallbladder as such can have nothing to do with this phenomenon of color changes in the bile.

Although the mentioned arguments are quite clear, it appeared worth while to repeat some of the given experiments and to increase their number in order to substantiate this view. This the more so as the power of the magnesium sulphate to evacuate the gallbladder contents is generally accepted among the profession.

The studies on the action of salts and other substances on the liver after their introduction into the duodenum have been repeated and amplified. Be-

*Read before the American Gastroenterological Association at Boston, Mass., June 7, 1921. (From the Lenox Hill Hospital.)

sides magnesium sulphate, sodium sulphate, sodium citrate and magnesium citrate, bicarbonate of soda, chloride of sodium, calomel, mercurchrome and a great many other substances have been added to the list of drugs used in the investigations.

The method used was identical with the one

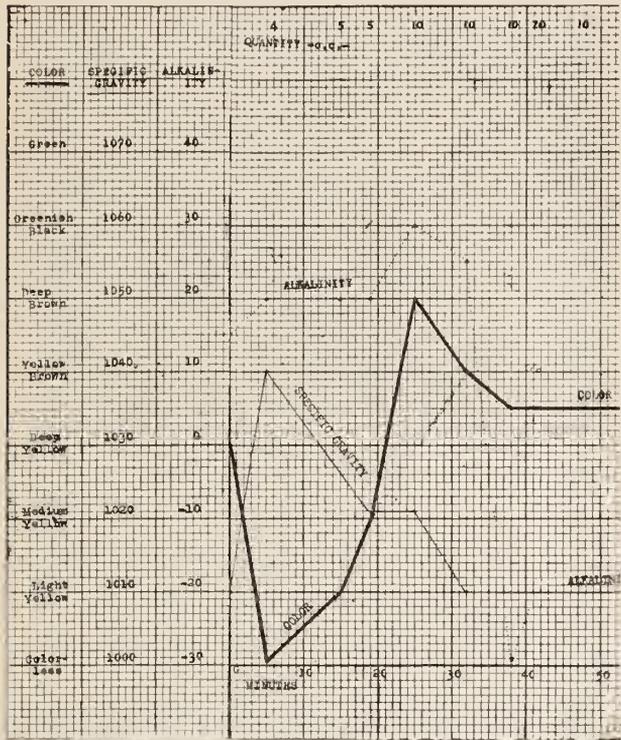

FIG. 1.—Mr. J. G. B. Magnesium sulphate twenty-five per cent., March 8, 1921.

described in the former paper, instilling a sixty c. c. solution of the desired salt or some other ingredient into the duodenum at blood temperature and then syphoning it back by gravity.

In the following cases the new investigations will be given in concise form, with a few graphic representations:

CASE I.—J. G. B., a patient with duodenal ulcer and chronic cholecystitis, had a complete series of different salts and other chemical ingredients instilled into the duodenum, so that a comparative study can be easily made. All these tests are briefly sketched and graphs given.

TEST I.

March 8, 1921. Magnesium sulphate, 25 per cent.

1. Fasting, orange yellow, very turbid; 10 c. c.; alk. = 15; s. g. = 1010.
2. After six minutes clear and watery; 4 c. c.; alk. = 20; s. g. = 1040.
3. After fifteen minutes light yellow, clear; 5 c. c.; alk. = 20.
4. After nineteen minutes shade darker yellow, clear; 5 c. c.; alk. = 20; s. g. = 1020.
5. After twenty minutes shade darker yellow; clear; 5 c. c.; alk. = 25.
6. After twenty-five minutes dark brown yellow, clear; 10 c. c.; alk. = 30; s. g. = 1020.
7. After thirty-two minutes lighter brown yellow, clear; 10 c. c.; alk. = 25; s. g. = 1010.
8. After thirty-eight minutes yellowish green, very turbid; 10 c. c.; HCl. = 15; Ac. = 30.

9. After forty-one minutes yellowish green, very turbid; 20 c. c.; HCl. = 10; Ac. = 20.
10. After forty-seven minutes yellowish green, very turbid; 10 c. c.; HCl. = 10; Ac. = 20.
11. After sixty minutes yellowish green, very turbid; 10 c. c.; HCl. = 10; Ac. = 20.
12. After sixty-two minutes clear, dark brown; 2 c. c.; alk. = 20.

TEST II.

March 20, 1921. Magnesium sulphate, 13 per cent.

1. Fasting, canary yellow, turbid; 4 c. c.; alk. = 15.
2. After three minutes light yellow, greenish tinge, slightly turbid; 4 c. c.; alk. = 20; s. g. = 1030.
3. After seven minutes dark yellow, brownish tinge, slightly turbid; 40 c. c.; alk. = 25; s. g. = 1010.
4. After fifteen minutes brownish yellow, slightly turbid; 40 c. c.; alk. = 30; s. g. = 1010.
5. After eighteen minutes golden yellow, clear; 30 c. c.; alk. = 20; s. g. = 1005.

TEST III.

March 17, 1921. Magnesium citrate, 13 per cent.

1. Fasting, turbid, canary yellow; 8 c. c.; HCl. = 10; Ac. = 20.
2. Fasting, slightly turbid, light yellow; 5 c. c.; alk. = 10; s. g. = 1010.
3. After three minutes watery, clear; 10 c. c.; alk. = 10; s. g. = 1010.
4. After ten minutes light yellow, greyish, turbid; 10 c. c.; HCl. = 5; Ac. = 10.
5. After fifteen minutes light canary yellow, turbid; 10 c. c.; alk. = 20; s. g. = 1005.
6. After twenty minutes light yellow, slightly turbid; 40 c. c.; alk. = 20.
7. After forty-five minutes dark yellow, turbid; 10 c. c.; alk. = 20; s. g. = 1005.

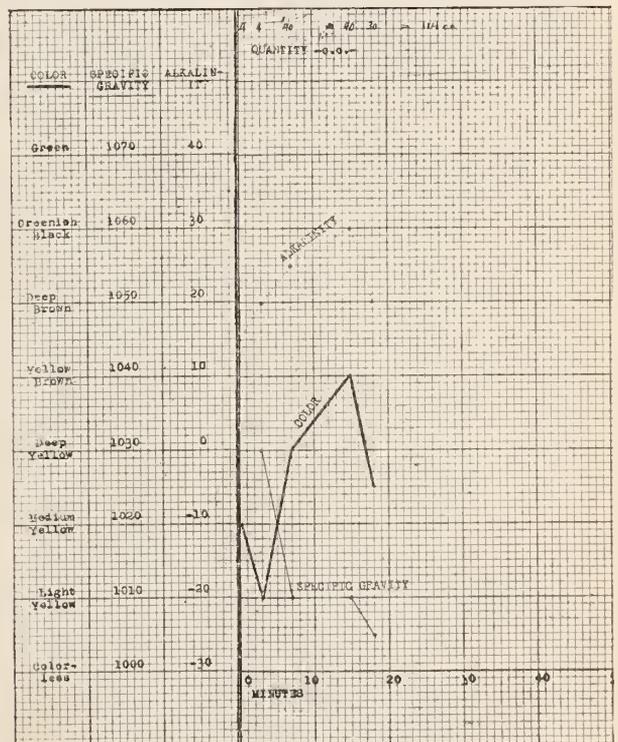

FIG. 2.—Mr. J. G. B. Magnesium sulphate thirteen per cent., March 20, 1921.

TEST IV.

March 9, 1921. Peptone, 5 per cent.

1. Fasting, canary yellow, turbid; 5 c. c.; alk. = 20; s. g. = 1010.
2. After four minutes greyish, turbid; 5 c. c.; alk. = 10; s. g. = 1010.

3. After seven minutes light yellow, slightly turbid; 3 c. c.; alk. = 25.
4. After eleven minutes dark brown yellow, clear; 5 c. c.; alk. = 25; s. g. = 1020.
5. After sixteen minutes light brown yellow, clear; 5 c. c.; alk. = 20.

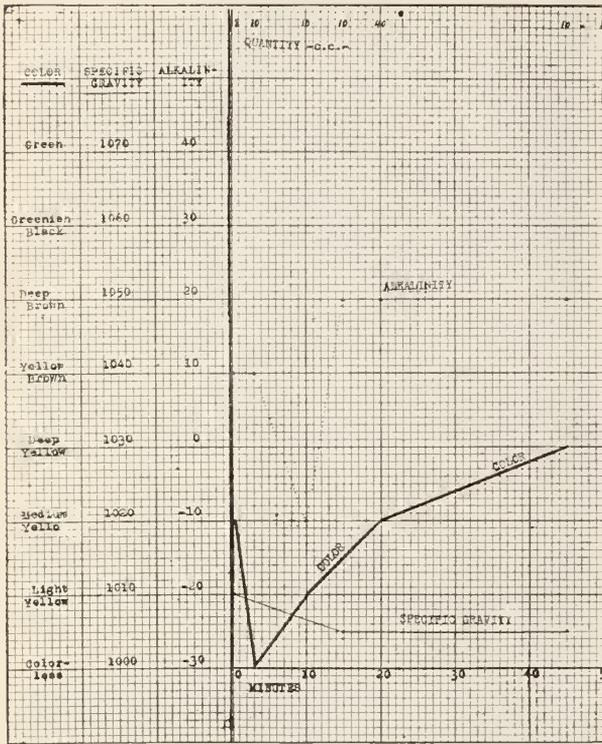

FIG. 3.—Mr. J. G. B. Magnesium citrate thirteen per cent., March 17, 1921.

6. After twenty-three minutes light brown, clear; 5 c. c.; alk. = 10.
7. After thirty minutes light yellow brown, clear; 5 c. c.; alk. = 10; s. g. = 1010.

TEST V.

March 12, 1921. Sodium bicarbonate, 8 per cent.

1. Fasting, canary yellow, turbid; 5 c. c.; alk. = 15.
2. After four minutes watery, clear; 5 c. c.; alk. = 25; s. g. = 1012.
3. After six minutes dark yellow brown, clear; 10 c. c.; alk. = 30; s. g. = 1020.
4. After nine minutes light yellow brown, clear; 5 c. c.; alk. = 20.
5. After twelve minutes dark yellow, turbid; 5 c. c.; alk. = 15; s. g. = 1010.

TEST VI.

March 10, 1921. Glucose, 25 per cent.

1. Fasting, canary yellow, slightly turbid; 5 c. c.; s. g. = 1010; alk. 20.
2. After two minutes clear, watery; 5 c. c.; s. g. = 1020.
3. After four minutes light yellow, clear; 10 c. c.; alk. = 20; s. g. = 1040; sugar = 1 per cent.
4. After six minutes dark brown yellow, clear; 10 c. c.; alk. = 25; s. g. = 1030.
5. After ten minutes light brown yellow, clear 5 c. c.; s. g. = 1030; alk. = 25.
6. After fifteen minutes darker brown yellow, clear; 5 c. c.; alk. = 30; s. g. = 1020.
7. After twenty minutes brownish yellow, greenish tinge, turbid; c. c.; alk. = 20; s. g. = 1010.
8. After thirty minutes light yellow, clear; 40 c. c.; alk. = 15.
9. After forty minutes light yellow, clear; 10 c. c.; alk. = 15; s. g. = 1010.

TEST VII.

March 11, 1921. Pilocarpine, 0.005 gm.

1. Canary yellow, turbid; 5 c. c.; s. g. = 1006; alk. = 10.
2. After ten minutes light yellow, clear; 10 c. c.; alk. = 10; s. g. = 1004.
3. After fifteen minutes canary yellow, turbid; 4 c. c.; alk. = 20; s. g. = 1004.
4. After twenty-five minutes light yellow, brownish, clear; 5 c. c.; alk. = 30; s. g. = 1005.
5. After twenty-five minutes dark brown yellow, clear; 10 c. c.; alk. = 30; s. g. = 1005.

TEST VIII.

March 14, 1921. Atropine sulphate, 0.0005 gm. in 60 c. c. of water.

1. Fasting, canary yellow, turbid, greenish tinge; 10 c. c.; alk. = 20; s. g. = 1015.
2. After four minutes, clear, watery; 5 c. c.; alk. = 20; s. g. = 1005.
3. After five minutes, canary yellow, turbid; 5 c. c.; alk. = 20.
4. After seven minutes light yellow brown, clear; 4 c. c.; alk. = 25.
5. After nine minutes dark yellow brown, clear; 5 c. c.; alk. = 35; s. g. = 1005.
6. After twenty minutes dark yellow brown, clear; alk. = 20; 5 c. c.
7. After thirty-eight minutes dark yellow, brownish tinge, clear; alk. = 20; 40 c. c.; s. g. = 1002.

TEST IX.

March 28, 1921. Mercurochrome, 0.5 per cent. in 60 c. c. of water.

1. Fasting, pea soup yellow, turbid; alk. = 20; s. g. = 1006; 10 c. c.
2. After three minutes very dark red, turbid; 5 c. c.; alk. = 15; s. g. = 1005.

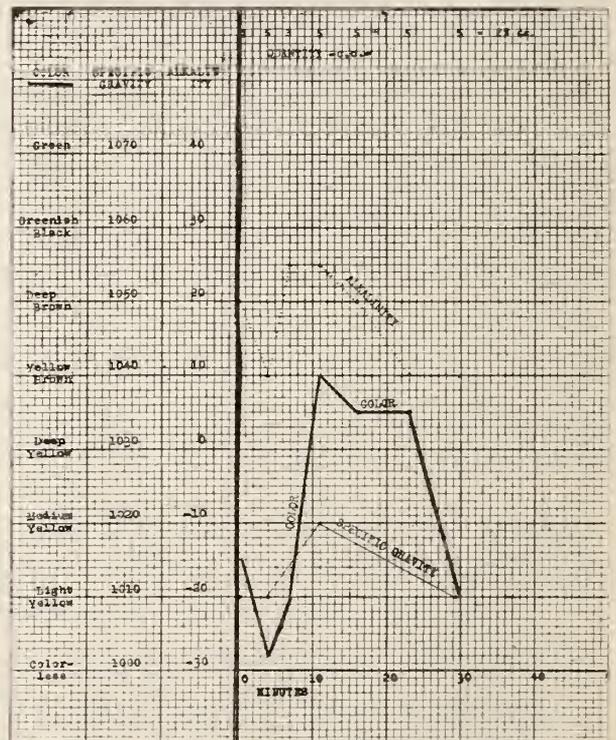

FIG. 4.—Mr. J. G. B. Peptone five per cent., March 9, 1921.

3. After seven minutes very dark red, yellow, turbid; 10 c. c.; s. g. = 1002; alk. = 20.
4. After fifteen minutes lighter red yellow, slightly turbid; 10 c. c.; alk. = 25; s. g. = 1002.
5. After twenty-five minutes light yellow, reddish, turbid; 10 c. c.; alk. = 35; s. g. = 1005.

6. After thirty minutes dark yellow, reddish, clear; 10 c. c.; alk. = 25; s. g. 1005.
7. After thirty-five minutes light yellow, reddish tinge, turbid; 10 c. c.; alk. = 30.
8. After fifty minutes light yellow, reddish tinge, turbid; 10 c. c.; alk. = 15; s. g. = 1010; (color altered by red of mercurochrome).

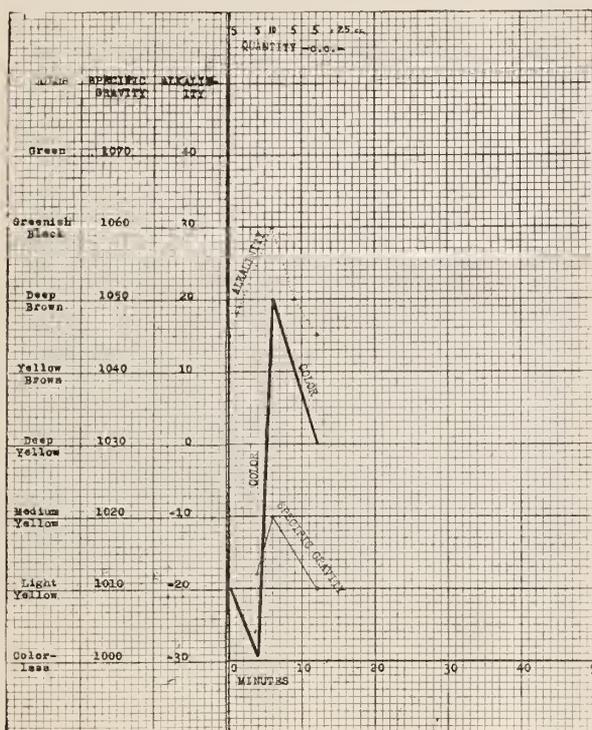

FIG. 5.—Mr. J. G. B. Sodium bicarbonate eight per cent., March 12, 1921.

TEST X.

March 11, 1921. Saline, 0.5 per cent.

1. Fasting, canary yellow, turbid; 5 c. c.; alk. = 20; s. g. = 1002.
2. After ten minutes watery, clear; 2 c. c.; alk. = 20.
3. After seventeen minutes light yellow, clear; 5 c. c.; alk. = 25; s. g. = 1010.
4. After thirty minutes light yellow, brownish, clear; 20 c. c.; alk. = 30; s. g. 1005.
5. After fifty minutes dark yellow, brown, clear; 40 c. c.; alk. = 20; s. g. = 1002

TEST XI.

March 19, 1921. Calomel, 0.06 gm. in 60 c. c. of water.

1. Fasting, canary yellow, greenish tinge, turbid; 15 c. c.; s. g. = 1010; alk. = 20.
2. After one minute watery, clear; 2 c. c.; alk. = 15; s. g. = 1010.
3. After nine minutes light yellow, turbid; 10 c. c.; alk. = 20; s. g. = 1012.
4. After eleven minutes dark yellow, clear; s. g. = 1020; alk. = 15; 40 c. c.
5. After twenty-nine minutes dark brown, yellow, clear; alk. = 15; s. g. = 1010; 15 c. c.

Fig. 1 (J. G. B.) shows the high specific gravity after twenty-five per cent. magnesium sulphate; the curve reaches 1040, when the salt partly returns with the light bile, then in the dark bile it is 1020, in order to go down with the lighter bile to 1010.

Fig. 2 (J. G. B.) gives the same items with the thirteen per cent. magnesium sulphate. The specific gravity in the light bile (from the admixture of the salt) gives a specific gravity of 1030, in the

dark bile 1010, and goes down in the lighter bile to 1006.

Comparing Figs. 1 and 2 one sees the influence of the greater concentration of magnesium sulphate on the height of the color reaction (reaching up to deep brown when twenty-five per cent. and yellow brown when thirteen per cent. was given) and the specific gravity, which is correspondingly lower, with the smaller concentration.

Fig. 3 (J. G. B.) shows the action of thirteen per cent. magnesium citrate which gives a very faint color reaction, in fact less than any of the other substances tried.

Fig. 4 (J. G. B.), five per cent. peptone, shows a good color reaction, with the specific gravity fluctuating between 1010 and 1020.

Fig. 5 (J. G. B.) shows a pronounced color reaction after eight per cent. bicarbonate of soda, with the specific gravity fluctuating between 1010 and 1020.

Fig. 6 (J. G. B.) shows an intense color reaction after the twenty-five per cent. glucose, with a specific gravity between 1010-1040.

Fig. 7, pilocarpine 0.005 gm.; Fig. 8, atropine 0.0005 gm.; Fig. 10, sodium chloride one half per cent., and Fig. 11, calomel 0.06 gm., all give good color reactions, with low specific gravities varying from 1006-1010. Fig. 9, mercurochrome, gives, likewise, a low specific gravity while the color reaction, although present, could not be illustrated on account of the admixture of the original red color.

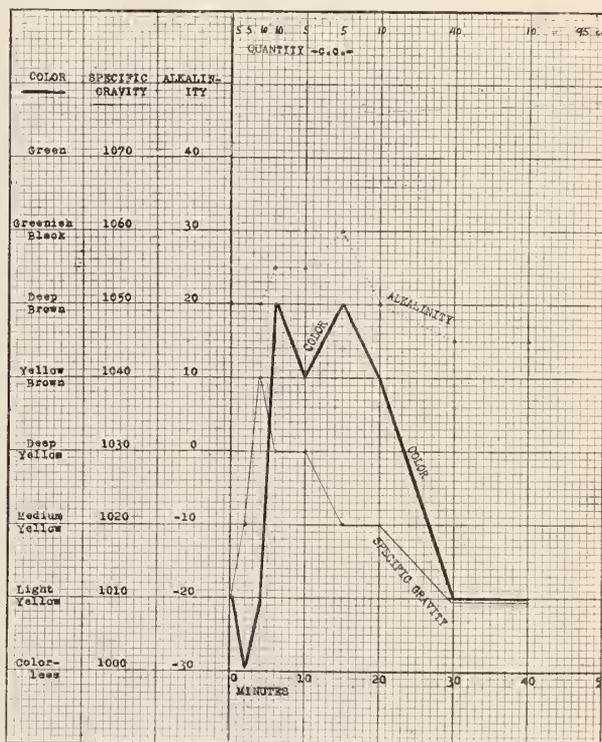

FIG. 6.—Mr. J. G. B. Glucose twenty-five per cent., March 10, 1921.

With regard to the quantity of bile excreted and in what time (or length of cycle) after the different ingredients, we find the following relations in the graphs of J. G. B.:

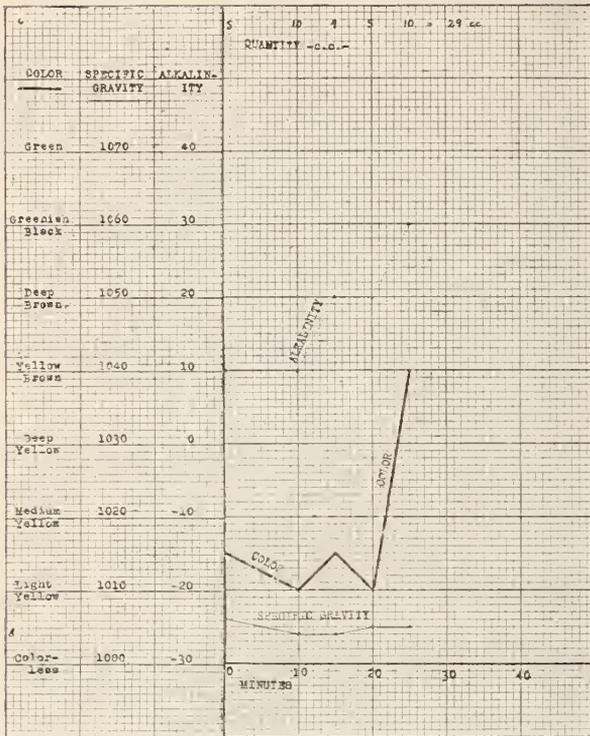

FIG. 7.—Mr. J. G. B. Pilocarpine 0.005 gram in sixty c.c. water, March 11, 1921.

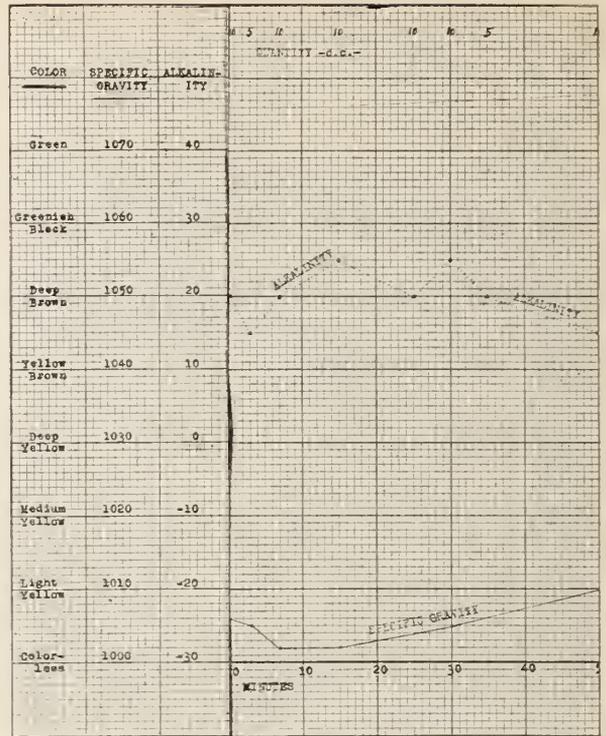

FIG. 9.—Mr. J. G. B. Mercurochrome one half per cent., March 21, 1921. (Color altered by presence of mercurochrome.)

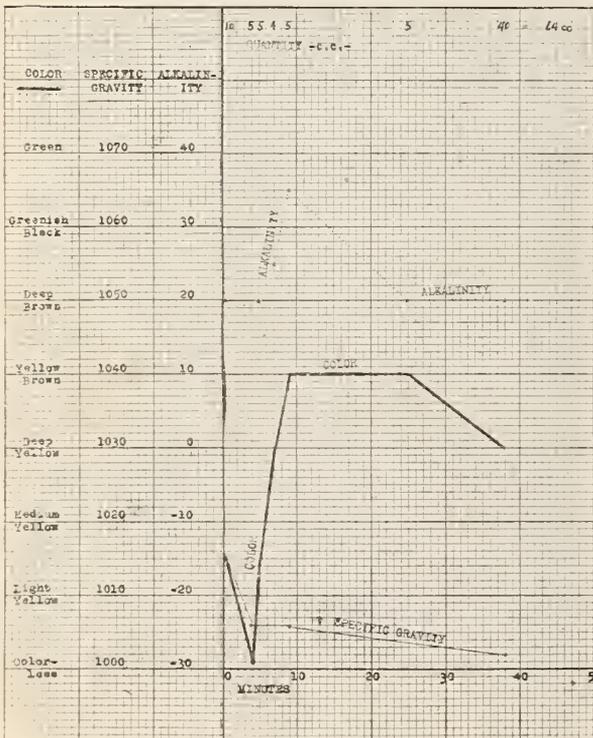

FIG. 8.—Mr. J. G. B. Atropine 0.0005 gram in sixty c.c. water, March 14, 1921.

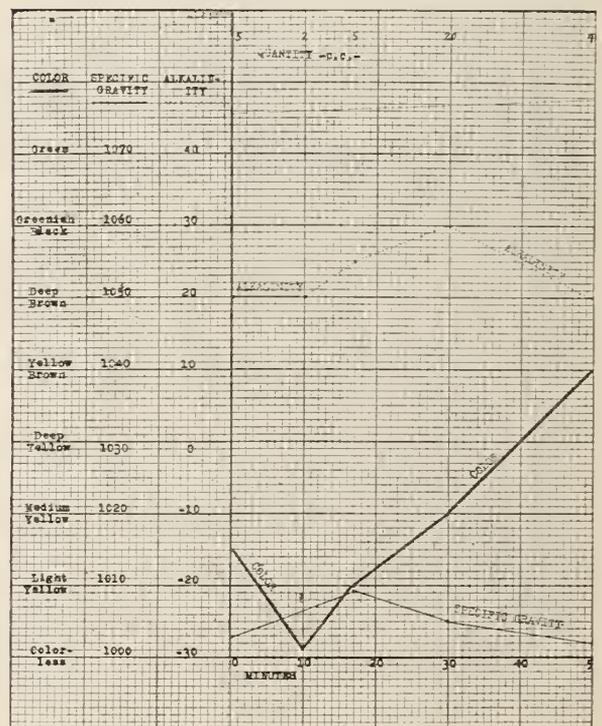

FIG. 10.—Mr. J. G. B. Sodium chloride one half per cent., March 11, 1921.

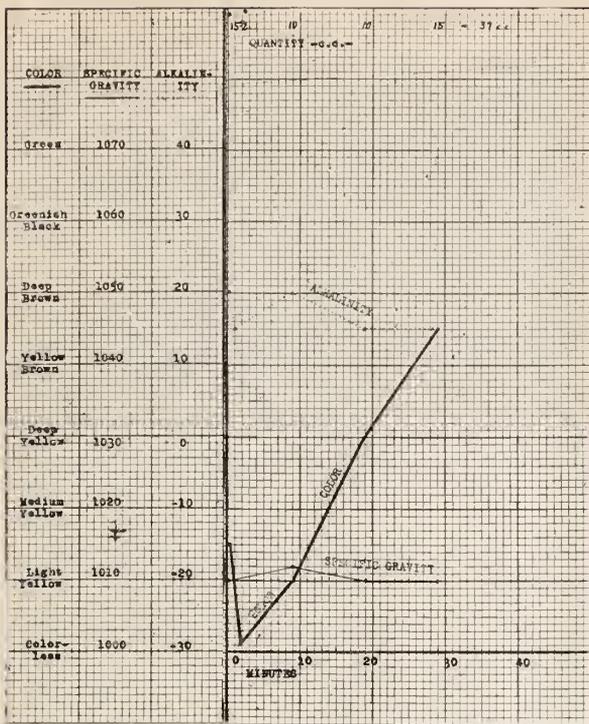

FIG. 11.—Mr. J. G. B. Calomel 0.06 gram in sixty c.c. water, March 19, 1921.

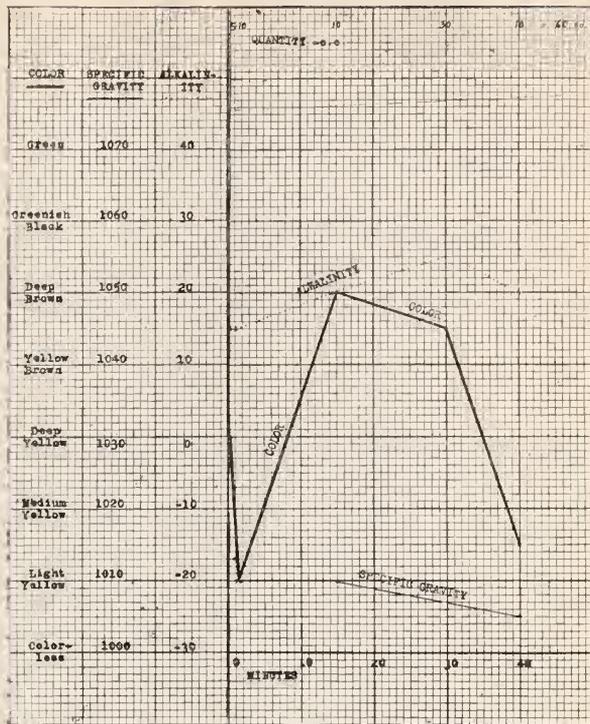

FIG. 13.—Mrs. Bella G. Cholecystectomy, peptone five per cent., March 25, 1921.

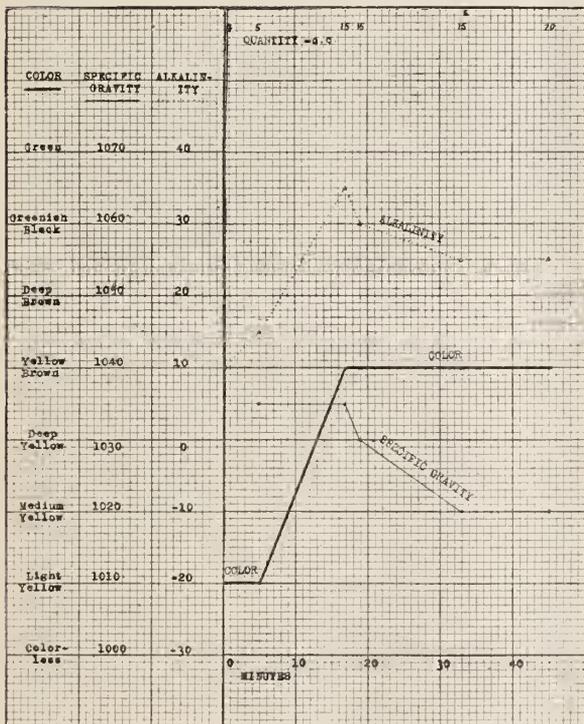

FIG. 12.—Mrs. Bella G. Cholecystectomy, magnesium sulphate twenty-five per cent., March 20, 1921.

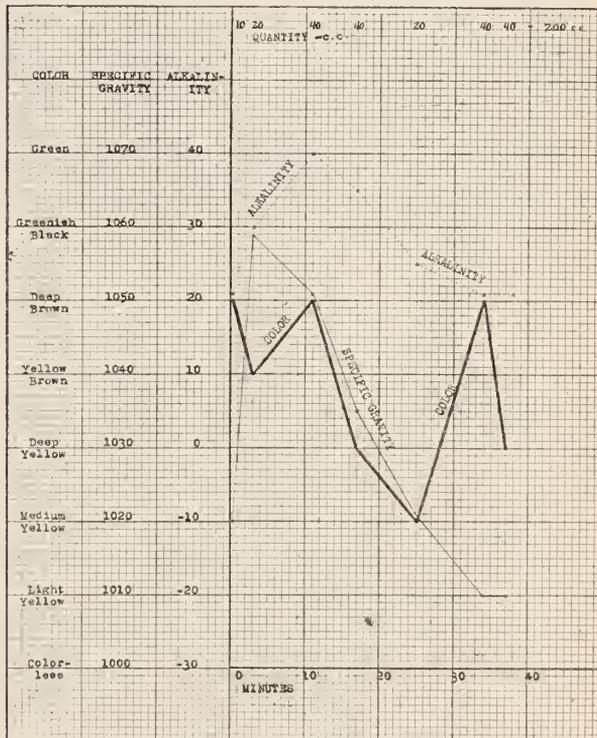

FIG. 14.—Miss Marie L. Cholecystectomy, magnesium sulphate twenty-five per cent., March 16, 1921.

Magnesium sulphate, 25 per cent.....	86 c.c.	60 min.
Magnesium sulphate, 13 per cent....	114 c.c.	18 min.
Magnesium citrate, 13 per cent.....	80 c.c.	46 min.
Peptone, 5 per cent.....	28 c.c.	30 min.

4. After thirty-five minutes light yellow, turbid; alk. = 15; s. g. = 1015; 40 c. c.

TEST III.

March 16, 1921. Sodium sulphate, 25 per cent.

1. Fasting, dark yellow, greenish tinge; 5 c. c; s. g. = 1010; alk. = 20.
2. After eight minutes greyish yellow, turbid; 15 c. c.; alk. = 25; s. g. = 1025.
3. After twenty minutes dark yellow, slightly turbid; 10 c. c.; alk. = 20; s. g. = 1020.
4. After thirty-five minutes very dark brown, yellow, turbid; 10 c. c.; alk. = 20; s. g. = 1010.

TEST IV.

March 19, 1921. Calomel, 0.06.

1. Fasting, dark yellow, turbid; alk.; 1 c. c.
2. After five minutes, watery, clear; alk. = 20; 2 c. c.
3. After ten minutes light yellow, turbid; alk. = 20; 4 c. c.
4. After twenty minutes dark yellow, greenish tinge, turbid; alk. = 25; 40 c. c.
5. After thirty minutes light yellow, turbid; alk. = 20; 5 c. c.

TEST V.

March 21, 1921. Mercurochrome, 0.5 per cent.

1. Fasting, light yellow, greenish tinge, turbid; 2 c. c.; alk. = 15.
2. After ten minutes dark red, clear; alk. = 15; 5 c. c.
3. After twenty minutes light red, turbid; alk. = 15; 5 c. c.
4. After thirty minutes canary yellow, turbid; alk. = 20; 10 c. c.; s. g. = 1010.
5. After thirty-five minutes dark green, yellow, turbid; 40 c. c.; alk. = 30; s. g. = 1010.
6. After fifty minutes pale red, turbid; alk. = 10; 5 c. c.

CASE III.—Isaac A., with gastric ulcer and chronic cholecystitis. The following ingredients were given alternately:

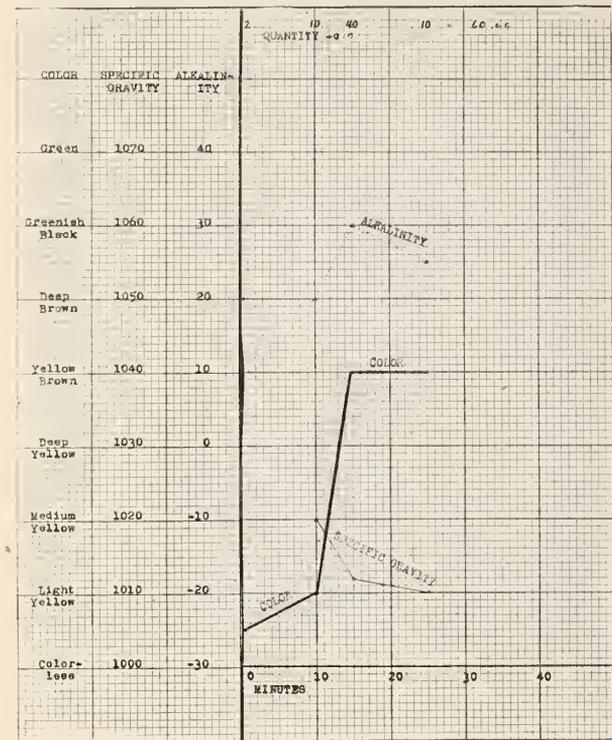

FIG. 15.—Miss Marie L. Cholecystectomy, peptone five per cent., March 25, 1921.

Sod. bicarbonate, 8 per cent.....	25 c.c.	12 min.
Glucose, 25 per cent.....	95 c.c.	40 min.
Pilocarpine, 0.005	29 c.c.	25 min.
Atropine, 0.0005	64 c.c.	38 min.
Mercurochrome, 1/2 per cent.....	60 c.c.	50 min.
Sodium chloride, 1/2 per cent.....	67 c.c.	50 min.
Calomel, 0.06	37 c.c.	29 min.

The largest amount of bile furnished was after thirteen per cent. magnesium sulphate, namely, 114 c. c. in eighteen minutes; the next highest is after glucose twenty-five per cent., ninety-five c. c. in forty minutes.

CASE II.—F. J. R., with probable cholecystitis. The following ingredients were tested:

TEST I.

March 14, 1921. Magnesium sulphate, 25 per cent.

1. Fasting, canary yellow, greenish tinge, turbid; 5 c. c.; alk. = 20; s. g. = 1010; (cholesterin crystals, pus cells, and mucus).
2. After one minute watery, clear; alk. = 20; s. g. = 1010; 5 c. c.
3. After three minutes light golden yellow, clear; alk. = 25; s. g. = 1020.
4. After twenty minutes very dark brown, greenish, yellow, turbid; alk. = 35; s. g. = 1030.
5. After thirty minutes shade lighter brown, greenish yellow; alk. = 30; s. g. = 1020.
6. After forty minutes shade lighter brown, greenish yellow; alk. = 30; s. g. = 1010.

TEST II.

March 20, 1921. Magnesium sulphate, 13 per cent.

1. Fasting, light canary yellow, turbid; alk. = 20; 4 c. c.
2. After ten minutes light yellow, clear, greenish tinge; s. g. = 1025; 10 c. c.; alk. = 20.
3. After twenty-five minutes turbid, very dark yellow; alk. = 30; s. g. = 1020; 20 c. c.

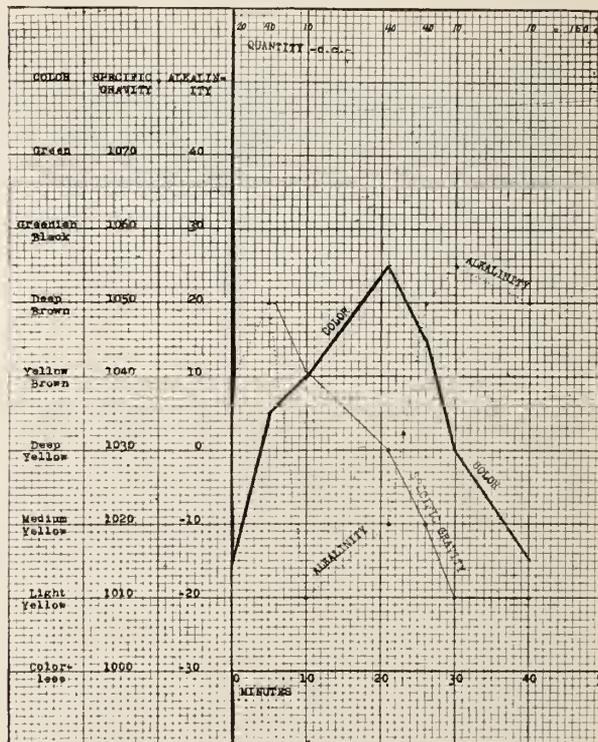

FIG. 16.—Mr. H. B. Before cholecystectomy, magnesium sulphate twenty-five per cent., March 20, 1921.

TEST I.

March 3, 1921. Magnesium sulphate, 25 per cent.

1. Fasting, light golden yellow, clear; alk. = 20; s. g. = 1010; 10 c. c.

2. After fifteen minutes golden yellow, clear; alk. = 25; s. g. = 1030; 10 c. c.
3. After twenty-five minutes dark yellow, slightly turbid; 5 c. c.; alk. = 25; s. g. = 1020.

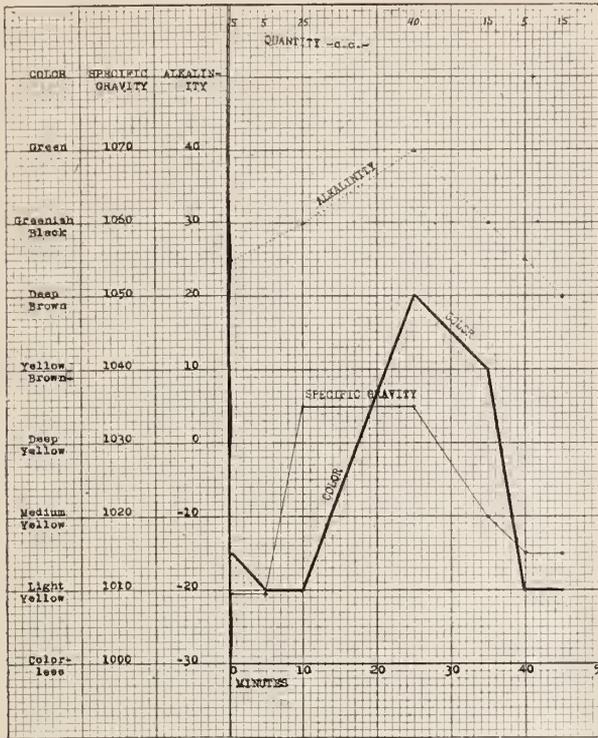

FIG. 17.—Mr. J. G. R. Magnesium sulphate twenty-five per cent., March 23, 1921.

4. After thirty-five minutes golden yellow, clear; alk. = 20; 10 c. c.
5. After forty-five minutes dark yellow, clear; alk. = 20; s. g. 1010; 5 c. c.

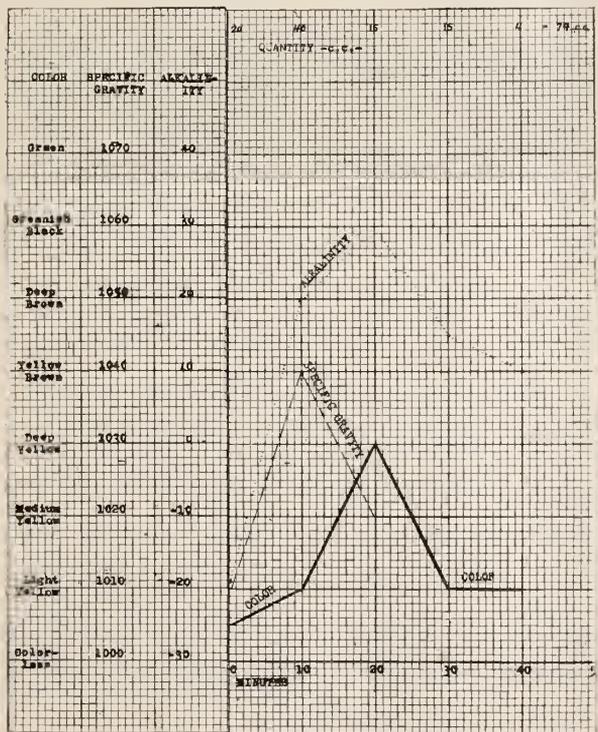

FIG. 18.—Mr. J. G. R. Sodium bicarbonate eight per cent., March 28, 1921.

TEST II.

March 5, 1921. Peptone, 5 per cent.

1. Fasting, dark yellow, turbid; alk. = 20; 10 c. c.
2. After fifteen minutes dark yellow, greenish tinge, turbid; alk. = 25; 8 c. c.
3. After twenty minutes dark yellow, greenish tinge; alk. = 25; 6 c. c.
4. After thirty minutes canary yellow, turbid; alk. = 20; 5 c. c.
5. After thirty-five minutes canary yellow; 5 c. c.; alk. = 20.

TEST III.

March 8, 1921. Magnesium citrate, 13 per cent.

1. Fasting, canary yellow, very turbid; 10 c. c.; HCl = 10; Ac. = 20.
2. After twenty minutes canary yellow, turbid; 10 c. c.; HCl = 10; Ac. = 20.
3. After thirty minutes light yellow, clear; alk. = 20; 10 c. c.
4. After forty minutes light yellow, clear; alk. = 20; 10 c. c.

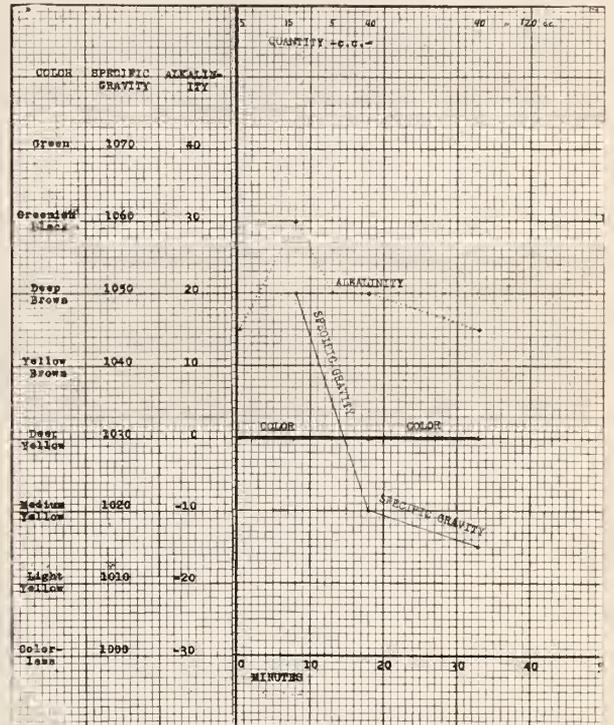

FIG. 19.—Mr. Henry S. Tumor of liver, magnesium sulphate twenty-five per cent., January 21, 1921.

TEST IV.

March 5, 1921. Sodium bicarbonate, 8 per cent.

1. Fasting, dark yellow, turbid; alk. = 20; 4 c. c.
2. After thirty minutes dark yellow, greenish tinge, clear; s. g. = 1030; 15 c. c.; alk. = 40.
3. After sixty minutes golden yellow, slightly turbid; s. g. = 1020; alk. 25; 10 c. c.
4. After one and one half hours golden yellow, turbid; s. g. = 1020; 15 c. c.; alk. = 20.
5. After two hours light yellow, slightly turbid; s. g. = 1010; alk. = 20; 4 c. c.

TEST V.

March 1, 1921. Saline, 3 per cent.

1. Fasting, light canary yellow, turbid; 10 c. c.; HCl. = 5; Ac. = 10.
2. After five minutes very light yellow, turbid; HCl. = 5; Ac. = 10; 10 c. c.
3. After ten minutes dark yellowish, brownish tinge; alk. = 25.
4. After twelve minutes very dark brown yellow, greenish tinge, clear; alk. = 25.
5. After fifteen minutes shade darker, brownish yellow, clear; alk. = 25.

TEST VI.

March 11, 1921. Saline, 0.5 per cent.

1. Fasting, yellow, slightly turbid; s. g. = 1006; alk. = 20; 5 c. c.
2. After twenty minutes light yellow, slightly turbid; alk. = 20; s. g. = 1010; 5 c. c.
3. After twenty-five minutes canary yellow, turbid; HCl. = 10; Ac. = 20; s. g. = 1012; 10 c. c.
4. After thirty minutes light golden yellow, clear; alk. = 25; s. g. = 1010; 8 c. c.
5. After forty minutes canary yellow, turbid; alk. = 20; s. g. = 1006; 8 c. c.

CASE IV.—Mrs. J. L. B., patient with duodenal ulcer and probable cholecystitis. The following ingredients were tested:

TEST I.

March 10, 1921. Glucose, 25 per cent.

1. Fasting, light canary yellow, turbid; alk. = 15; s. g. = 1020.
2. After ten minutes watery, clear; alk. = 15.
3. After twenty minutes light canary yellow, slightly turbid; alk. = 20; s. g. = 1040.
4. After thirty minutes very light yellow, clear; alk. = 20; s. g. = 1030.

TEST II.

March 11, 1921. Saline, 0.5 per cent.

1. Fasting, brownish yellow, slightly turbid; s. g. = 1005; alk. = 20; 5 c. c.
2. After ten minutes watery, slightly turbid; s. g. = 1004; alk. = 20; 4 c. c.
3. After twenty minutes light brownish yellow, clear; alk. = 25; 10 c. c.
4. After forty-five minutes brownish yellow, clear; s. g. = 1002; 40 c. c.

TEST III.

March 15, 1921. Pilocarpin, 0.005 gm. in 60 c. c.

1. Fasting, canary yellow, turbid; s. g. = 1010; 5 c. c.
2. After one minute clear, watery; s. g. = 1002; 2 c. c.
3. After thirty minutes canary yellow; turbid; s. g. = 1002; 5 c. c.
4. After forty-five minutes dark yellow, brownish tinge; turbid; s. g. = 1000; 10 c. c. (patient vomited).

TEST IV.

March 14, 1921. Atropine sulphate, 0.0005 gm. in 60 c. c. of water.

1. Fasting, canary yellow, turbid; alk. = 15; s. g. = 1010; 5 c. c.
2. After four minutes light canary yellow, clear; alk. = 15; 5 c. c.
3. After ten minutes dark yellow, brownish tinge, clear; alk. = 15; s. g. = 1010; 5 c. c.
4. After fifteen minutes light yellow, brownish tinge, clear; alk. = 20; 10 c. c.
5. After twenty minutes light yellow brownish tinge, clear; 10 c. c. alk. = 20; s. g. = 1005.

CASE V.—Fabian B., patient with achylia gastrica and cholecystitis. The following substances were given:

TEST I.

March 25, 1921. Magnesium sulphate, 25 per cent.

1. Fasting, light yellow, turbid; alk. = 20; 4 c. c. A. = 10; S. = 1; T. = 0.
2. After eight minutes light straw yellow, clear; s. g. = 1030; 5 c. c.
3. After twenty minutes dark yellow, turbid; s. g. = 1030; 5 c. c.
4. After fifty minutes very dark brownish green, turbid; s. g. = 1025; 40 c. c.
5. After fifty-five minutes light yellow brown, clear; s. g. = 1020; 5 c. c.
6. After sixty minutes light yellow brown, clear; s. g. = 1020; 3 c. c.
7. After sixty-five minutes light yellow, turbid; s. g. = 1015; 5 c. c.

TEST II.

March 12, 1921. Peptone, 5 per cent.

1. Fasting, greyish; no bile; alk. = 10; s. g. = 1010; 15 c. c.
2. After two minutes greyish, no bile; alk. = 15; 10 c. c.
3. After four minutes dark yellow, turbid; alk. = 15; 5 c. c.
4. After thirteen minutes very dark yellow, turbid; 15 c. c.; alk. = 20; s. g. = 1012.
5. After fourteen minutes dark yellow, turbid; alk. = 20; 4 c. c.
6. After twenty-eight minutes lighter dark yellow, turbid; alk. = 20; 3 c. c.
7. After fifty minutes very dark yellow, turbid; alk. = 20; s. g. = 1010; 40 c. c.
8. After fifty-five minutes lighter dark yellow, turbid; 5 c. c.; alk. = 10.
9. After fifty-seven minutes lighter yellow; 5 c. c.; alk. = 15.

TEST III.

March 19, 1921. Glucose, 20 per cent.

1. Fasting, greyish turbid; alk. = 10; 2 c. c.
2. After seventeen minutes watery, clear; s. g. = 1040; alk. = 10; 50 c. c.
3. After forty minutes dark yellow, turbid; s. g. = 1020; alk. = 20; 20 c. c.
4. After fifty minutes shade lighter yellow, turbid; alk. = 25; 15 c. c.
5. After fifty-six minutes greyish, turbid; alk. = 10; 10 c. c.

A number of other patients were given the different salts mentioned and also various medicaments. The present article would become too cumbersome should they all be described. Suffice it to say that similar reactions although in various gradations, were obtained in most patients from all the ingredients tested. The specific gravity of the dark bile was increased, when the substance given had a high specific gravity (magnesium sulphate, glucose) and not increased when the substances ingested did not influence it, like peptone, calomel, atropine, pilocarpine, etc.

Four new cases, patients with cholecystectomies, Mrs. B. G., Miss M. L., Mrs. C. S., and Mrs. Y. S., gave a good reaction with magnesium sulphate and also with a five per cent. peptone solution. Studies of two of these cases, Mrs. B. G. and Miss M. L., are illustrated in graphs (Figs. 12 to 15). Here also as in patients with the presence of a gallbladder the specific gravity of the dark bile after magnesium sulphate is much higher than in the dark specimen obtained after the peptone instillation. In fact all the substances producing reaction (dark bile) do it whether the gallbladder is present or not. It is evident that the gallbladder as such has nothing whatever to do with this phenomenon.

Dr. Willy Meyer and I were able to furnish another positive proof that the dark bile need not come from the gallbladder, but can be eliminated from the liver directly. The following instance demonstrated this very clearly:

Patient H. B., with cholecystitis, was given magnesium sulphate on the day previous to operation. He gave a characteristic dark color bile reaction as the following notes from our notebook demonstrated and as the subjoined graph (Fig. 16) shows:

CASE VI.—Mr. H. B., with chronic cholecystitis.

TEST I.

March 21, 1921. Magnesium sulphate, 25 per cent.

1. Fasting, pea soup appearance, yellow, turbid; alk. = 10; 20 c. c.

2. After five minutes dark yellow brown, greenish tinge, turbid; 40 c. c.; alk. = 20; s. g. = 1050.

3. After ten minutes brownish yellow, turbid; 10 c. c.; HCl = 10; Ac. = 20; s. g. = 1040.

4. After twenty-one minutes dark brown yellow, greenish tinge; 40 c. c.; s. g. = 1030; HCl = 5; Ac. = 10.

5. After twenty-six minutes yellowish green on upper three-quarter; dark brown yellow on lower one-quarter; 40 c. c.; s. g. = 1020; alk. = 20.

6. After thirty minutes greenish yellow, turbid; 10 c. c.; alk. = 25; s. g. = 1010.

7. After forty minutes light yellow, brown, turbid; alk. = 20; s. g. = 1010; 10 c. c.

TEST II.

March 23, 1921. Magnesium sulphate, 25 per cent.

1. Fasting, light yellow, very turbid; alk. = 20.

2. After eleven minutes light yellow, greenish tinge, turbid; alk. = 35; s. g. = 1016.

3. After thirty minutes light greenish yellow, slightly turbid; s. g. = 1060; alk. = 30.

At the operation (the duodenal tube had been left *in situ*) two important points were ascertained: 1, magnesium sulphate was given through the tube; after waiting from five to ten minutes no dark bile was obtained. The gallbladder which was exposed and constantly observed did not show any contractions; 2, at the operation the cystic duct was found tightly closed by a stone so that nothing could leave or enter the gallbladder. Moreover, after opening the latter, the contents were found to have a reddish appearance and consisting of pus and red blood corpuscles mixed with mucus, without any bile.

Inasmuch as there has been no bile in the gallbladder and this condition must have existed for quite some time and inasmuch as nothing could enter or leave the vesicular cavity, the dark bile obtained the day previous could not have originated from this source and must of necessity have come from the liver ducts (choledochus).

In a few rare instances the color reaction of the bile after magnesium sulphate appears quite abruptly, lasts a little while and suddenly ceases. In these cases it would be natural to assume that the dark colored bile came from the gallbladder as a result of the relaxing action of the magnesium salt. This, however, does not seem to be the case, for in these patients other salts, especially bicarbonate of soda, or other liver irritants will do the same, showing that this phenomenon is not due to an evacuation of the gallbladder contents. As an illustration two graphs are given (Figs. 17 and 18).

CASE VII.—John G. R., patient with duodenal ulcer and chronic cholecystitis.

TEST I.

March 23, 1921. Magnesium sulphate, 25 per cent.

1. Fasting, watery, canary yellow, turbid; 5 c. c.; s. g. = 1010; alk. = 15.

2. After five minutes yellow, watery; s. g. = 1010; 5 c. c.

3. After ten minutes light yellow, greenish tinge, turbid; alk. = 30; s. g. = 1035; 15 c. c.

4. After twenty-five minutes very dark brown, turbid; alk. = 40; s. g. = 1035; 40 c. c.

5. After thirty-five minutes light brown, turbid; alk. = 30; s. g. = 1020; 15 c. c.

6. After forty minutes very light yellow, brownish tinge, slightly turbid; alk. = 25; s. g. = 1015; 5 c. c.

7. After forty-five minutes light yellow, slightly turbid; alk. = 20; s. g. = 1015; 15 c. c.

TEST II.

March 28, 1921. Bicarbonate of soda, 8 per cent.

1. Fasting, very light yellow, turbid; 20 c. c.; HCl. = 10; Ac. = 20.

2. After ten minutes light yellow, clear; s. g. = 1040; alk. = 20; 40 c. c.

3. After twenty minutes dark yellow, slightly turbid; alk. = 30; s. g. = 1020; 15 c. c.

4. After thirty minutes light yellow, clear; alk. = 15; s. g. = 1020; 15 c. c.

5. After forty minutes light yellow, clear; alk. = 10; 4 c. c.

The difference in the specific gravity of the dark bile after magnesium sulphate and that after the bicarbonate of soda clearly indicates that this process is not due to a mere release of concentrated bile from the bladder, but rather to a chemical action on the liver. Thus the higher concentration of the magnesium salt (twenty-five per cent.) caused an elimination of a bile of a higher specific gravity than bicarbonate of soda (eight to nine per cent.).

From my experiences with different salts and other chemical ingredients when injected into the duodenum, it is apparent that the liver can be induced to a greater activity to an elimination of a darker, more concentrated bile.

As mentioned in my former paper on this subject, injections of these substances into the duodenum can be conveniently used as a functional test of the activity of the liver. Magnesium sulphate, sodium sulphate, peptone, glucose solutions, also bicarbonate of soda, appear to be appropriate for this purpose.

We give here three new cases of severe liver lesions in which this color reaction of the bile after the injection of these liver stimulants into the duodenum did not show up. One of these cases is given in Fig. 19. The others are briefly described.

CASE VIII.—S., patient with cancer of the liver.

TEST I.

January 21, 1921. Magnesium sulphate, 25 per cent.

1. Fasting, dark yellow, turbid; 5 c. c.; alk. = 15.

2. After eight minutes dark yellow, clear; alk. = 30; s. g. = 1050; 15 c. c.

3. After thirteen minutes dark yellow, turbid; alk. = 20; 5 c. c.

4. After eighteen minutes dark yellow, turbid; alk. = 20; s. g. = 1020; 40 c. c.

5. After thirty-three minutes very dark yellow, turbid; s. g. = 1015; alk. = 15; 40 c. c.

CASE IX.—Mrs. A. A.; January 18, 1921; patient with subnutrition and chronic cholecystitis.

TEST I.

Magnesium sulphate, 25 per cent.

1. Fasting, dark yellow, turbid; alk. = 15; 5 c. c.

2. After five minutes light yellow, clear; alk. = 15; 5 c. c.

3. After eleven minutes light yellow, slightly turbid; alk. = 20; 5 c. c.

4. After twenty-one minutes dark yellow, turbid; alk. = 20; s. g. = 1030; 15 c. c.

5. After forty-three minutes shade lighter yellow, turbid; alk. = 20; 10 c. c.

6. After fifty-two minutes dark yellow, clear; alk. = 20; 4 c. c.

TEST II.

Mrs. A. January 15, 1921. Sodium sulphate, 25 per cent.

1. Fasting, dark yellow, greenish tinge; alk. = 16; 10 c. c.

2. After three minutes light golden yellow, turbid; alk. = 15; 5 c. c.

3. After eleven minutes light golden yellow, turbid; alk. = 20; 10 c. c.

4. After seventeen minutes light golden yellow, turbid; alk. = 15; 10 c. c.

5. After twenty-two minutes yellow, turbid; HCl. = 5; Ac. = 10; 5 c. c.

6. After twenty-eight minutes light golden yellow, turbid; alk. = 10; 5 c. c.

7. After thirty-five minutes dark yellow, slightly turbid; alk. = 15; 5 c. c.

TEST III.

January 22, 1921. Glucose, 20 per cent.

1. Fasting, light yellow, turbid; alk. = 15; 3 c. c.

2. After five minutes light yellow, turbid; alk. = 20; 5 c. c.; s. g. = 1060.

3. After ten minutes light yellow, turbid; s. g. = 1045; alk. = 20; 10 c. c.

4. After twenty minutes light yellow, clear; s. g. = 1030; alk. = 15; 5 c. c.

CASE X.—Mrs. Anna R., with cholecystitis and cirrhosis of the liver (with jaundice); March 21, 1921. Twenty-five per cent. magnesium sulphate.

TEST I.

1. Fasting, greyish, tinge of yellow, turbid; alk. = 10; 2 c. c.

2. After eight minutes light yellow, clear; alk. = 10; 5 c. c.

3. After ten minutes light greenish yellow, slightly turbid; alk. = 20; s. g. = 1025; 40 c. c.

4. After forty minutes yellowish, greenish tinge, turbid; alk. = 20; s. g. = 1020; 40 c. c.

TEST II.

March 28, 1921. Sodium bicarbonate, 8 per cent.

1. Fasting, light green yellow, clear; alk. = 10; 10 c. c.

2. After ten minutes light green yellow, clear; alk. = 20; 20 c. c.

3. After fifteen minutes dark green yellow, clear; alk. = 20; 30 c. c.

Lyon had suggested the employment of the magnesium sulphate instillation as a means of diagnosis in gallbladder lesions and also for the differentiation of the different biles (from gallbladder, common duct, and hepatic duct).

As shown before and again in this paper Lyon's assumption of the different sources of bile, as judged by the color, does not seem to be correct.

The question arises what are the best conditions for the examination of the bile in gallbladder lesions.

Inasmuch as the magnesium sulphate and other liver stimulants increase the flow of bile from the liver and drive it, so to say, quickly and directly into the duodenum, there will be after these substances a bile product from the liver direct containing very little if any bile from the gallbladder. In the fasting condition and without any previous stimulation the aspiration succeeds in obtaining what little bile there is in the duodenum from the liver and the gall bladder, or there seems to be more chance for the appearance of some gallbladder bile when the flow of liver bile is not extensive.

In practising bile examinations in the fasting state of the patient, for the last ten years or so, I found this to be the case.

Diagnostically, then, we can find many more valuable hints regarding gallbladder lesions from the examination of the natural fasting bile than from the bile obtained after the stimulation by magnesium sulphate.

In cases of jaundice, however, in which no bile is found in the fasting state, a liver stimulant may be injected into the duodenum, in order to ascertain whether the increased flow of bile from the liver is still able to push through some of its products into the duodenum. In fact, in a number of such cases of chronic jaundice with no bile in the duodenum while fasting, the magnesium sulphate caused the appearance of some bile after a short time, thus showing that the common duct occlusion was not complete. In these cases the magnesium sulphate or peptone or glucose test is of diagnostic aid.

Before I conclude this paper I wish to thank Dr. Willy Meyer and Dr. Terek for permission to examine their cases and Dr. H. Bockus, Dr. H. Puhlman and Dr. H. A. Rafsky for assisting in carrying out the investigations.

Clinical Gastric Analysis with Detail of Method and a Consideration of the Maximum Information to Be Obtained*

By B. B. VINCENT LYON, A. B., M. D.,

HENRY J. BARTLE, B. S., M. D.,

and

RICHARD T. ELLISON, B. S., M. D.,

Philadelphia.

We have not endeavored to present anything particularly new in this study, but it is rather our purpose to present in detail a practical, clinical method of performing a fractional gastric analysis and also to reemphasize the statements of other writers that the estimation of the acid values is the least important of the many points that can be learned from such an examination when intelligently conducted. We wish particularly to stress a few points which to us seem important, and to amplify

certain microscopic observations which are helpful in arriving at a diagnosis. The method to be outlined we have found practical for both dispensary and private practice, and the information obtained has amply repaid us for the large amount of time consumed in securing detailed facts.

No two fractional charts can be compared unless they have both been done under identical conditions and the same points noted for each, and the obvious advantages of a standard technic are seen when an attempt is being made to analyze the deviations from normal in any given chart. This is even of

*Read before the American Gastroenterological Association, Boston, Mass., June 6, 1921.

greater importance when two charts from the same patient are being analyzed. We also wish to emphasize the need of investigation into the associated findings of the stomach, other than the acid values. These include the presence of mucus and bile, and the addition of pathological products, such as bacteria, pus, blood and tissue juices. These associated findings all have a direct influence on the interpretation of the acid curves and also yield much information as to the intragastric and extragastric pathology.

We will not enter here into a discussion of the relative merits of fractional analysis versus the single extraction method, other than to say that we agree with Best (1), who says: "The advantage of these curves in their superiority over the older one sample test is comparable to the advantage of the moving picture over a single snapshot."

It has only been since 1914 that fractional gastric analysis has been in general use. At that time Rehfuess (2) revived the fractional method and gave it a fresh impetus by using the small sized tube with metal tip. In this and subsequent papers this investigator laid down certain fundamental principles of fractional analysis to which subsequent writers have been able to add little of vital importance. So-called normals, as well as abnormals, were studied by Rehfuess and Hawk, Best, Rutz, and others to determine a normal curve and institute a standard. But since the type of normal curve could not be stabilized, other investigations took place involving the enzyme action of gastric and duodenal juices, together with microscopic observations of fasting and digesting stomach contents.

The fractional analysis method is simple, safe and extremely sane, and is a method not only of choice but one of necessity where gastric function is to be studied. Who of us would think of returning to the one hour test extraction after he had experienced the value of the information to be obtained by the fractional study method. It presents for your elucidation, graphically recorded if you so desire, the acid values of the contents of the stomach at any time you may care to estimate them. Errors of secretion and motility of either the fasting or the digesting stomach can be observed. The time of duodenal reflex can be checked up and matched with the appearance of blood, pus, or duodenal exfoliation in the stomach; a strong confirmatory observation in suspected duodenal ulcer, if they should be coincidental. The time of mucoid impregnation of the contents can be estimated, and microscopic examination can be made of the fasting and digesting residues.

METHOD OF ANALYSIS.

But, to turn now to the detailed description of our method of performing the actual test. Each patient is given the following typewritten instructions preparatory to presenting himself for a gastric analysis:

"At nine o'clock the night before examination eat one meat sandwich (any kind of meat) with twenty raisins or six stewed prunes, and drink a glass of water or cambric tea. Eat or drink nothing after this, either during the night or early morning, until we give it to you in this office at nine

a. m. Do not brush teeth on morning of examination."

This motor meal is to be taken twelve hours before the test is to be started, the principal object of the long fast being to have the stomach empty so as to get a true picture of both the acidity and microscopy of the interdigestive stomach. The purpose in not brushing the teeth is to avoid trauma to the gums with the subsequent misinterpretation of the swallowed blood when found in the stomach. The patient is warned against swallowing post-nasal discharge and bronchial excretion during his waking state.

When the patient presents himself a small sized gastrointestinal tube, with any one of the various metal tips, is passed into the stomach. Note is made of the way the patient takes the tube, whether quietly or with retching, and to what extent the gag reflex is manifested (vago-tonia versus sympathico-tonia) and evidence of cardiospasm watched for. The entire contents of the stomach should be gently lifted out and saved for subsequent examination. The patient is then instructed to place the tube on one side of the throat bringing it out into the buccal space behind the last molar, and in this position he will find that it interferes very little with his comfort in eating the test meal.

In the selection of a test meal we agree with Rehfuess (3), who says: "A fixed test load, simple and accessible, readily withdrawn, and capable of showing both secretory and motor variations, as well as pathological products, is a *sine qua non* as the basis of intelligent analysis of the stomach," and we have long used the true classical Ewald meal of fifty grams of white bread and 350 c.c. of water (as personally taught by Ewald to one of us in Berlin in 1914). Approximately fifty grams of bread is represented by two half inch slices of white bread, three inches by three inches, with the crust cut off.

From the time of the last swallow of bread and water up until the tube is finally removed at the completion of the test, the patient is instructed to expectorate the saliva into a receptacle. The object is twofold; first, to prevent its obscuring the analysis by mechanical interference, and by lowering the acid curve; and second, by recording its amount, an added bit of information is obtained relative to vago-tonia (hyperptyalism) and enzyme activity can be estimated. More attention should be paid to salivary examinations.

Fifteen minute extractions are now made over an average period of two hours, making eight extractions in all. The first seven of these are not to exceed ten c.c. each, and each amount is to be measured and recorded, but at the two hour extraction the stomach is entirely emptied and the amount recovered is to be measured and recorded. The material from each extraction is filtered through gauze or linen, and the filter then tested for starch with iodine solution. In this way the point at which the stomach becomes empty can readily be determined. If the stomach does empty before the two hour period an attempt should be made to continue the extraction of gastric secretion to the end of the two hour test, as much additional information may

thus be obtained. When the stomach is emptied at two hours it is then lavaged with 250 c.c. of water to prove not only that it is empty of the fluid part of the meal, but also that it is empty of bread crumbs which may remain in dependent portions or in gastric crypts. The tube is then removed.

This portion of the test being completed the collected material is examined immediately, if possible. This point is of importance, since evaporation of the samples increases their acidity, and the continuation of digestion changes the relation of free and combined hydrochloric acid. Each sample is examined grossly for amount, chyme, mucus and bile, and chemically for free hydrochloric acid, total acid and occult blood. The fasting stomach content should always be examined microscopically. In testing for acid one c.c. of filtrate is titrated against one one hundredth sodium hydroxide, of which the number of c.c. is multiplied by ten, giving the degrees of acidity for each 100 c.c. of gastric contents. Dimethyldiamidoazobenzol and phenolsulphonaphthalein are used as indicators. In testing for occult blood either a freshly prepared solution of benzidine or the commercial occult blood tablets are to be used. Rutz (4) has shown that hematin granules have a tendency to adhere to other particles in suspension and that, therefore, the sediment gives a more delicate reaction.

With the figures obtained from the titrations a graphic chart of the changes in acidity is constructed, using the degrees of acidity as ordinate and time as abscissa, and making thirty minutes the equivalent of 30°. The total amount of material withdrawn is computed and this is subtracted from the 350 c.c. originally given, and therefore the amount that has passed the pylorus can be noted and a clinical estimation of gastric motility is thus obtained.

We wish here to refer to a further procedure that was first advanced by one of us (Lyon) in 1915 of obtaining the contents of the stomach crypts. The mouth and throat are rinsed and gargled with an astringent mouth wash (liquor zinci formaldehyde) followed by a one grain to the ounce aqueous solution of potassium permanganate, and again with sterile water. The sterile tube is then introduced, and the fasting residuum aspirated and the stomach is washed with 250 c.c. of sterile water at body temperature run in the tube through a glass container elevated about two feet above the patient's mouth, and immediately siphoned to a 250 c.c. graduate on the floor. The inflow and outflow durations are recorded, inasmuch as we feel that this gives us certain clinical data relative to the

state of tonicity of the gastric wall. Repeated washing is done until the return is crystal clear, and unless there is marked gross retention this is usually accomplished in from two to three washings. Then 250 c.c. of a weak solution of zinc chloride and formalin is run in and allowed to remain for one minute, when it is siphoned off. This acts as an astringent and causes the mucous membrane to contract, and the secretions in the ducts are forced out and appear as floccules in the subsequent washings. These floccules are pipetted out of the solution and examined microscopically, or the complete

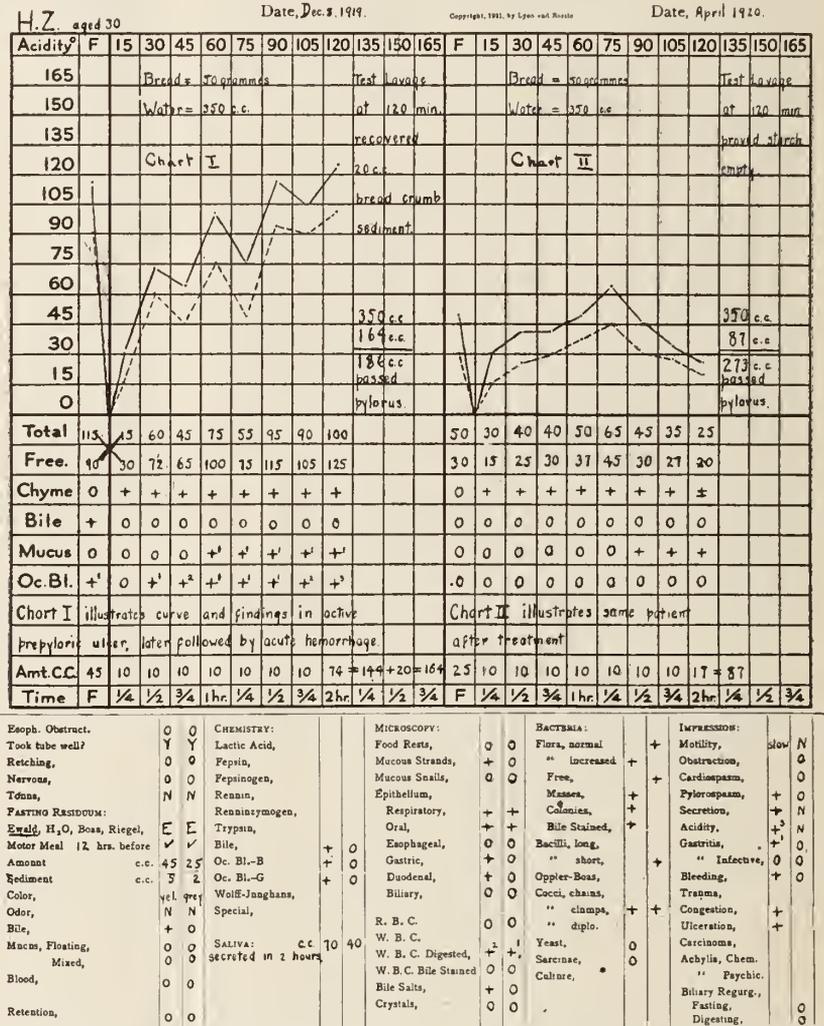

CHART I.—Curve and findings in active prepyloric ulcer, later followed by acute hemorrhage. CHART II.—Curve and findings in same patient after treatment.

sediment may be collected and run through a hardening process, mounted in celloidin and sectioned and stained and examined by microscope, just as any pathological specimen is handled. The technic of the method was presented in 1915 (5), and has proved of great help to us in keeping permanent records of intragastric pathology.

Gastric analysis is primarily a measure of gastric work, fasting and digesting, motor and secretory, as has been pointed out by Rehfuess and Hawk (6), and in order to measure the work done and compare it with a normal, a standard test load must be given the stomach to handle. This measure of work is in reality the measure of the physiological function

of the stomach, secretory and motor, and any deviation from the normal in either acid values or motor activity must be viewed only in the light of pathological physiology. But gastric analysis when intelligently conducted is more than just a measure of the work done, it is an indicator of true intragastric pathology. The evidence of such pathology, however, lies in the addition to the gastric juice of the products of that pathology. These are mucus, exfoliated epithelial elements, pus, blood, and bacterial colonies. And there is a third and equally important side to gastric analysis, namely, that it

findings of regurgitated duodenal epithelium, pus, mucus, and bacteria.

Whenever there is any deviation from the normal values in a given gastric analysis it is of the utmost importance from the clinicians' viewpoint to determine whether these variations are due to intragastric pathology, or are the indirect evidence of conditions outside the stomach. But before the deviations from normal can be appreciated it is necessary that we have some conception of what constitutes normal findings in a test conducted as outlined above. We will, therefore, briefly discuss what we consider to be normal findings as found in patients who not only have no gastrointestinal ailments, but are also free from any general or other local conditions. We will also point out the chief types of pathological curves.

TO CONSIDER FIRST THE TWELVE HOUR FASTING STOMACH CONTENTS.

The amount varies in health from a few cubic centimetres to fifty to eighty c.c., anything above that amount being due either to hypersecretion or retention, that question being decided by the microscopic picture. Sediment up to five per cent. of the total amount recovered cannot be considered beyond normal limits. Mucus that floats is generally freshly swallowed, whereas the type of very viscid, stringy, intimately mixed mucus is usually associated with absence of free hydrochloric acid at that particular period of the gastric cycle. We have found the acid values of the fasting stomach to vary within wide limits. Attention has been called by different writers to the fast and slow motility of normal stomachs, and we feel that there should be a comparable secretory classification of high and low stomachs both within normal limits. It would seem that this question of fast and slow, high and low, is often dependent on the habitus of

the individual, and that this fact must be kept in mind. This accounts for the variations in the acid values in different persons, but we have also found that if the stomach contents of the same individual are examined daily under the same conditions of time, and length of preceding fast, great variations of acid values will also frequently be seen. The explanation of this is, we believe, that the level of acidity in the interdigestive stomach is an expression of a vital function, and like other vital functions it fluctuates from day to day and is easily influenced by such things as loss of sleep, worry, nervousness, or overeating, drinking or smoking the night before the examination.

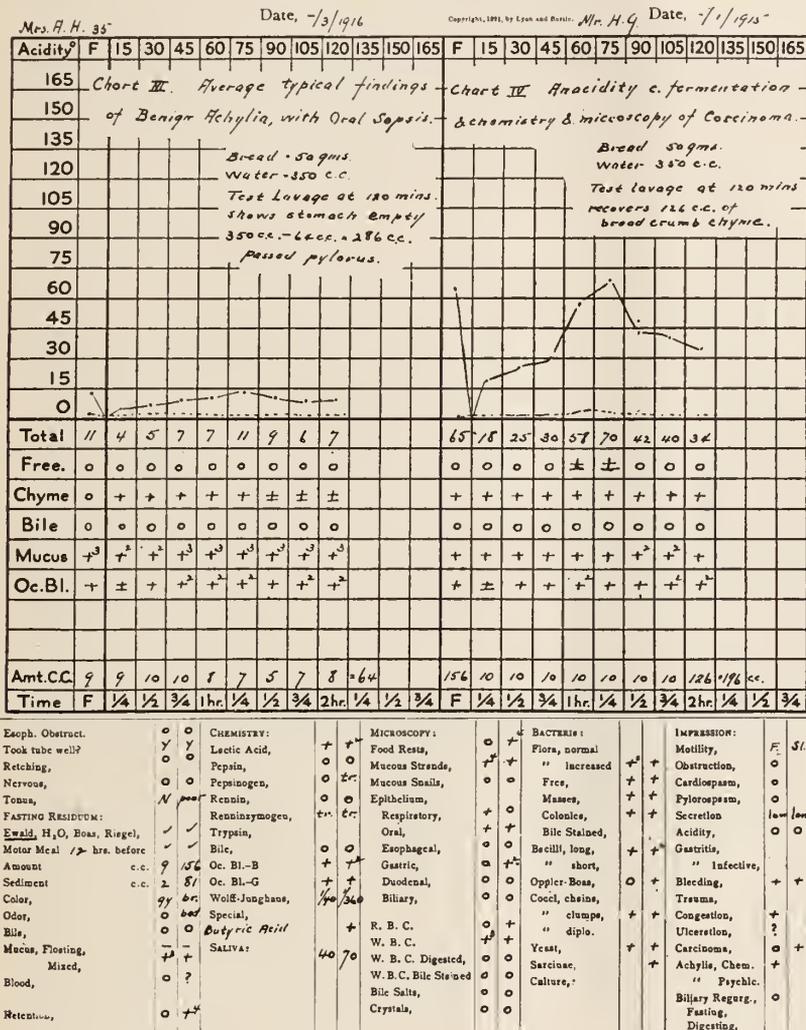

CHART III.—Average typical findings of benign achylia with oral sepsis.

CHART IV.—Anacidity with fermentation and chemistry and microscopy of carcinoma.

serves as an indicator of extragastric pathology. It has long been recognized that most systemic conditions, and many strictly local conditions, even though far removed from the stomach, may influence that viscus. The evidence of such influence is seen indirectly in its effect on the acid curves, and directly by the finding of products of this extragastric pathology added to the gastric secretions. Examples of this latter are the finding of swallowed pus from various sources and the occurrence of occult blood associated with biliary regurgitation which, according to Rehfuess (7), is the only direct evidence of duodenal ulcer to be obtained from a gastric analysis (Chart I). To this should be added the

be seen in the same sediment, and if so each must be examined and the relative amounts noted.

In making a preparation for microscopic examination a small amount of the material is placed on a slide and a cover slip dropped on top. We prefer routinely to use unstained preparations except when searching for particular elements when various differential stains may be used. On looking at this with the high power objective it will be seen that either the cells are practically intact or that the cytoplasm is entirely digested away (Fig. 1), leaving only the more resistant nuclei. The nuclear

and respiratory tract for evidence of infection (Fig. 2). In an acid stomach both the chief and parietal types of gastric cells can be seen, but it must be remembered that these, as well as other cells, are dead or dying, and usually show cloudy swelling (Fig. 3).

In regurgitation from the duodenum the cytology is usually very well preserved if an examination is made promptly. Duodenal cells (round, cuboidal, or oval cells somewhat longer than pus cells) can be recognized, and at times bile stained columnar epithelium from the biliary tract can be seen. The very tall bile stained columnar epithelium we believe is only derivable from the gallbladder. Bile stained pus cells, when found in association with this latter type of epithelium, point to infection somewhere in the duodenobiliary tract (Fig. 4). When bile is regurgitated into a stomach containing free hydrochloric acid, the bile salts are precipitated, giving the material grossly a turbid appearance, and microscopically appear as small clumps and masses of yellow amorphous material. When such regurgitation takes place in an anacid stomach there is no such precipitation. Bile that has remained in the acid stomach for some time assumes various shades of blue and green, due to oxidation or other chemical changes and can readily be differentiated from freshly regurgitated bile from gagging or under reflex causation.

Normally there is no gross or microscopic evidence of food retention in the twelve hour fasting stomach. Retention when found is not pathognomonic of any one pathological process, but it is frequently enough associated with graver conditions in and about the pylorus to necessitate a careful investigation into the causative factor. (Atony, pylorospasm, adhesions, stenoses from inflammatory edema, hypertrophy or from new growth within or without.)

The question of the bacterial flora of the stomach is one upon which much still remains to be written. Bacterial bodies can always be found in the stomach, but whether they are living organisms, and whether they are truly resident in the stomach, constituting an infected gastritis, or only in transit, are points of vital importance to determine. To answer the second question first, bacteria that are in transit are seen as single organisms or grouped in small masses. If, however, visible organisms linger long enough to become implanted in the gastric mucosa they grow in colony formation (Fig. 3) just as colonies grow on the surface of any suitable media.

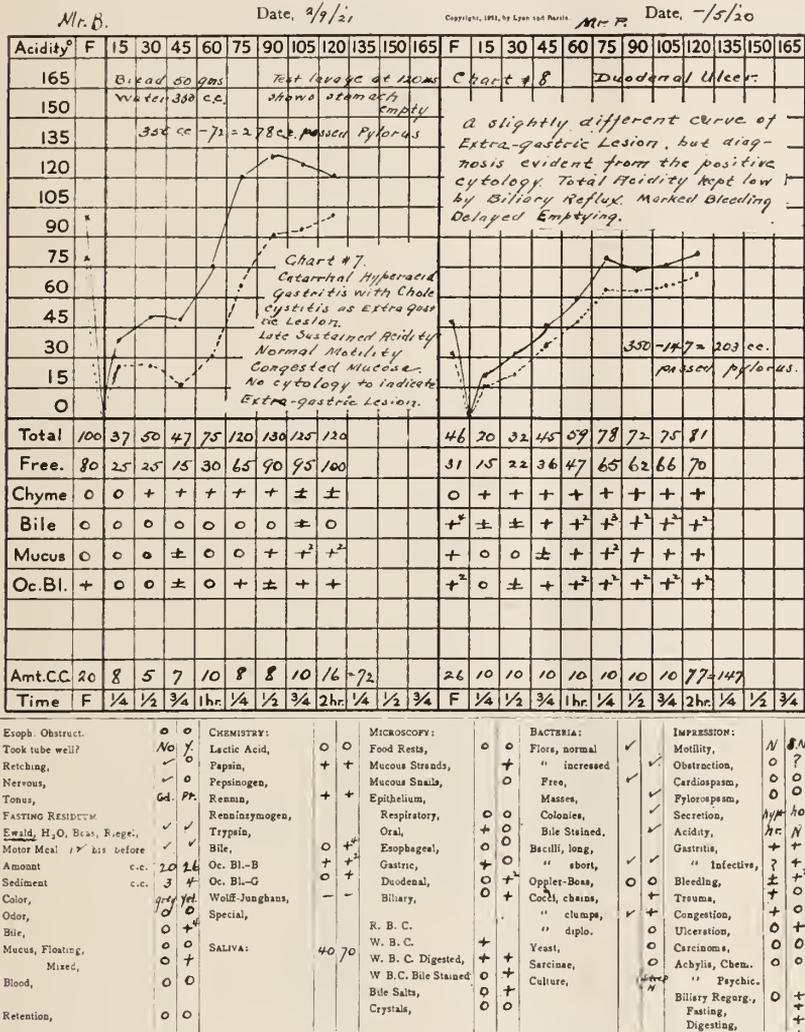

CHART VII.—Catarrhal hyperacid gastritis with cholecystitis as extragastric lesion. Late sustained acidity, normal motility, congested mucosa. No cytology to indicate extragastric lesion.

CHART VIII.—Duodenal ulcer. A slightly different curve of extragastric lesion, but diagnosis evident from the positive cytology. Total acidity kept low by biliary reflux. Marked bleeding delayed emptying.

remains of gastric cells are oval, highly refractive bodies, and the polymorphonuclear cells are seen as groups of two or three small globules. There is always a certain number of leucocytic cells in the fasting stomach, but if these occur in sufficient numbers to constitute pus, they are a distinctly pathological factor. The type of epithelium with which the pus is associated is the deciding factor in locating the point of its discharge, and the finding of a predominance of buccal or respiratory epithelium should lead to a careful search of the mouth

When they become detached and are seen in the fasting stomach contents they are entirely similar to the surface colonies of a Petri culture plate when viewed through a low power ocular. The final answer to the question of viability must depend on culturation, but we feel that for all practical purposes the finding of colonies associated with gastric mucus or epithelium is positive proof of the presence of infection in the gastric mucosa. Particularly is this so if they occur conspicuously in the floccules pressed out from the gastric tubules after washing the stomach clean and then rewashing with an astringent solution. The colonies are microscopically here found associated with exfoliated gastric epithelium, pus cells and inflammatory debris.

To the finding of occult blood in the fasting stomach we do not attach much importance unless the benzidene reaction be very strong and the guaiac reaction positive. This is because, in spite of the precaution taken, it is generally extragastric in origin. It is only definitely of value when the nasopharyngeal and bronchial secretions have been proved to give negative reactions.

Having completed the examination of the fasting stomach content, the next point in the examination is the analysis of the type of curve obtained. We agree with Best (1) who says, "The actual acid value means very little. The shape of the curve means more," and with Rehfuess (9) who says, "There is no pathognomonic curve in any gastric condition," and yet we feel very strongly that there are certain types of curves that point to certain conditions. From a study of many analyses we find that they all fell into one of five groups. Any of these groups, with the exception of the third, can be associated with either hyperacidity or subacidity. The question of the amount of acid secreted in response to the

stimulation of the test meal seems to us to depend on the irritability of the vagus, and the state of fatigue or integrity of the gastric glandulature.

Type I. Normal curve. This is the type of curve in which the apex is reached in from sixty to seventy-five minutes, and a return to within 15° of the fasting values occurs at 120 minutes. It is the type of curve seen in perfectly healthy persons and also in certain early states of intragastric conditions—principally catarrhal. The points indicative of an early catarrhal process are gastric mucopus in the fasting stomach content, and mucus and perhaps traces of blood in the digesting stomach.

Type II. Extragastric curve (Charts VII and VIII). In this type the curve rises steadily during the entire two hour period, or until the stomach becomes empty if there is an associated hypomotility. This is the type of curve that is usually found due to reflex irritation from pathology outside the stomach. It is frequently seen in cases of duodenitis, duodenal ulcer, gallbladder conditions, appendicitis and sigmoiditis. It may be found in association with a clean stomach or with all the evidence of a high grade infected gastritis, but in either case the principal source of

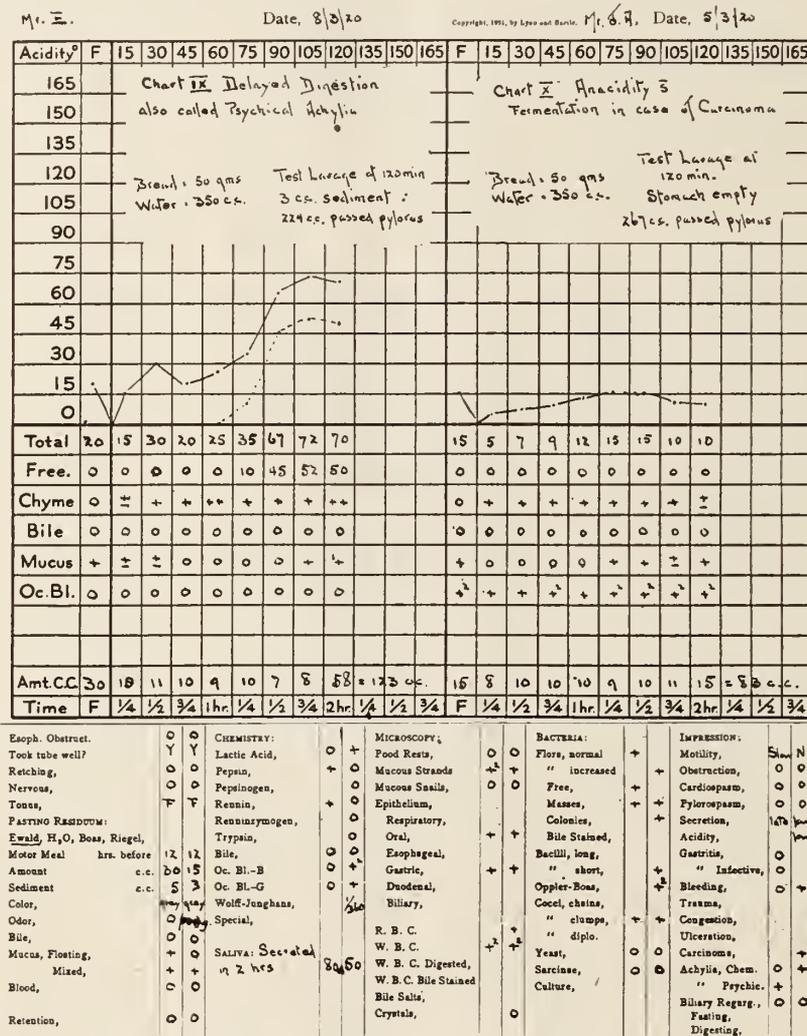

CHART IX.—Delayed digestion, also called psychological achylia. CHART X.—Anacidity without fermentation in case of carcinoma.

trouble is extragastric. (Exception: functional pylorospasm.)

Type III. Achylia. This is a type of curve in which there is no free hydrochloric acid present at any time. It is most frequently seen in cases of malignancy of the stomach in the later stages, in oral sepsis, long standing cholelithiasis, and in the severe anemias, either primary or secondary. Differentiation of the type of achylia comes from the testing of gastric filtrates for organic acids proenzymes and for the soluble albumin and from the microscopic picture. (Charts III, IV, and X.)

Type IV. Stepladder curve. In this type of

curve the smooth ascent is broken by drops in both free hydrochloric and total acid, unassociated with biliary regurgitation, followed by a rise to a still higher level than that preceding the drop (Chart I). This curve is not often seen, but is of grave signifi-

A possible explanation of this type of curve is that the primary rise represents the psychic secretion, and the secondary rise the hormonal secretion. This latter, which should normally pick up and carry on the psychic secretion, is delayed, and therefore per-

FIG. 1.—Hyperacid catarrhal gastritis; A, buccal epithelium digested; B, nuclear remains of digested gastric cells; C, nuclear remains of digested leucocytes; D, mucus spirals (myelin?) in "snail" forms; E, bacteria in clumps and masses.

cance. We have only seen it in ulcer cases in the active stages, and it is generally preceded or followed by hemorrhage. Best (1) illustrates a curve of this type, and notes that there was a recent hemorrhage.

Type V. Delayed digestion curve. In this curve

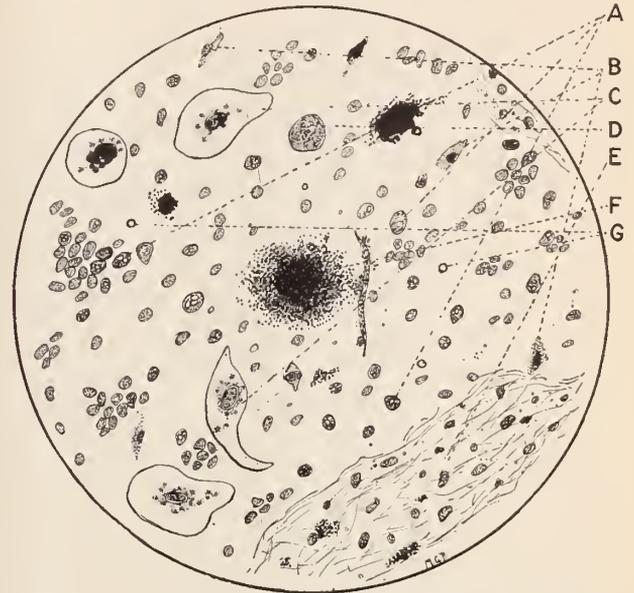

FIG. 3.—Anacid gastritis; A, pus cells, with cloudy swelling of protoplasm, predominating feature; B, gastric epithelium, degenerated; C, buccal epithelium; D, salivary corpuscle; E, strand of mucus, with bacteria and pus cells; F, colony of bacteria; G, red blood corpuscles.

mits of a wearing off of the psychic stimulus and a consequent drop in the acid values.

In addition to the study of the fasting stomach content, and an analysis of the type of curve, there are certain other findings which must be tabulated.

FIG. 2.—Gastric subacidity, with extragastric cytology; A, respiratory and buccal epithelial cells; B, salivary corpuscles; C, leucocytes or pus cells with protoplasm intact; D, colony of cocci; E, occasional gastric epithelial cells.

there is a primary small rise followed by a drop, and then by a practically normal curve. In certain cases of this type the free hydrochloric acid does not come in until the secondary rise, and it corresponds to the psychical achylia of some writers (Chart IX).

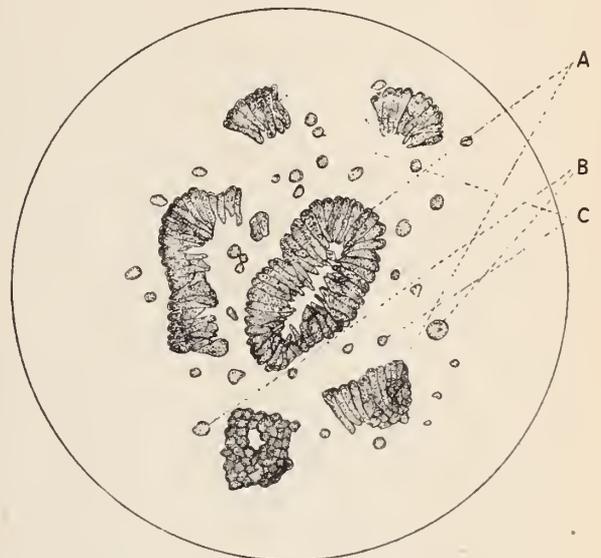

FIG. 4.—Catarrhal exfoliative cholecystitis; A, tall bile stained columnar epithelium from gallbladder, arranged in fan shapes and rosette clusters; B, oval or cuboidal duodenal epithelial cells; C, pus cells or leucocytes, appearing much like duodenal cells but usually smaller. Note: The nuclei can be brought out by adding dilute acetic acid.

The motor element is of great importance, and when carried out as detailed earlier in this paper, we believe will give a more accurate estimate of gastric motility than the x ray examination for six hour

barium retention or from any other unphysiological test meal. In all cases of achylia the associated tests mentioned above should be done. The details of these reactions do not fall within the scope of this paper, but can be found in any standard work on the stomach.

Mucus, when found in all the extractions, especially when associated with low salivary output (gauged by measuring the amount of saliva spat out during the two hour test), is probably swallowed; whereas mucus, appearing only in the second half of the examination, is generally gastric in origin. The interpretation of bile in the digesting stomach has been discussed above and need not be repeated here. The finding of blood in the digesting stomach must not be taken as evidence of ulcer or neoplasm unless the evidence of careful history and physical and x ray examinations lend their support to such a diagnosis. It is more often to be interpreted as mucosal congestion with diapedesis, or due to miliary erosions, and should lead to a careful examination of heart, lungs and liver and for obstruction in the portal circulation. We consider the finding of occult blood in the gastric filtrates as of much more importance than its demonstration in the gastric residues. The number of times that it appears in the fractional analysis also adds greater significance to its finding.

In closing we want to say a word about the diag-

nostic and prognostic value of repeated fractional gastric analyses. We have found this method of checking our findings of the greatest practical value (Charts I and II). It is especially useful in cases where repeated x ray examinations cannot be obtained, because it gives a very accurate picture of the motility of the stomach, as well as its secretory curve. It has also been of value in following the progress of medical treatment, and in estimating the benefit derived from surgical interference (Charts V and VI). In many cases, with complete arrest of symptoms, it will be found that the fractional analysis has not returned to normal, and unless treatment is continued a relapse is quite likely.

Personal Experiences with Nonsurgical Biliary Drainage*

By JULIUS FRIEDENWALD, M. D.,
Baltimore,

Professor of Gastroenterology, University of Maryland,
and

THEODORE H. MORRISON, M. D.,
Baltimore,

Associate in Gastroenterology, University of Maryland.

It is a well recognized fact that the medical treatment of gallbladder affections has been quite unsatisfactory, and that even surgery does not always afford the relief which should be expected from procedures of this character. The very fact, for instance, that the choice between such operative procedures as cholecystostomy and cholecystectomy has not as yet been fully established among surgeons is evidence sufficient to attest to the truth of this assertion. Disregarding the immediate operative risk, which is usually slight, the subsequent results as they are observed by the family physician months, or even years later, in the form of recurrence of pain due to a return of the original affection or adhesions, producing digestive disturbances of various forms, are all too frequently the evidence of unsatisfactory operative measures, which are alike distressing to the patient as well as to the physician. It is on this account that we must welcome any new measure that may render the diag-

nosis as well as the treatment of biliary affections more satisfactory.

Based on Meltzer's observation that a twenty-five per cent. solution of magnesium sulphate introduced locally into the duodenum causes a relaxation of the sphincter of the common duct and according to his law of contrary innervation a contraction of the gallbladder, Lyon evolved his method of diagnosis as well as a method of nonsurgical biliary drainage. This plan has marked an advance in the study and treatment of these affections. We have employed this method in cases totalling three hundred and fifteen single observations. The technic is quite simple and in many instances the treatment has been carried out for us by nurses and later on by the patients themselves.

DESCRIPTION OF PROCEDURE.

With but few minor modifications the original plan of Lyon's has been followed. The patient is instructed to fast, and with the exception of a glass of water, if this is desired, nothing else is allowed

*From the Gastroenterological Clinic of the Mercy Hospital, Baltimore, Maryland.

after ten p. m. on the evening before the treatment is instituted. At nine a. m. on the following day, after the teeth have been brushed thoroughly, the mouth cleansed and throat gargled with an antiseptic solution, the tip of a freshly sterilized duodenal tube is placed in the back of the mouth and swallowed with a sip of water. After the tube passes into the stomach, lavage is practised at first with water until the wash water is returned sparkling clear and again with 250 c. c. of a one to 10,000 solution of potassium permanganate, as much as possible of which is immediately recovered. We have practised lavage of the stomach when obtaining cultures only to avoid contaminations and when considerable mucus was present in the stomach. The patient is then ordered to lie on the right side and to swallow very slowly an additional twenty cm. of the tube totalling a distance of from seventy-five to eighty cm. from the incisor teeth. This process should consume about twenty minutes. During this procedure swallowing efforts are repeated at regular intervals. A large swallow of water frequently facilitates the passage of the tube into the duodenum. At times the passage into the duodenum is accomplished in ten minutes and rarely does it consume longer than an hour. Before proceeding further it is necessary to determine whether entrance into the duodenum has been effected. According to our experience, the most reliable evidence in this respect is the change occurring in the color and character of the aspirated fluid. The fluid assumes a canary yellow color which soon turns to an amber hue; and the character changes from a tenacious mucoid liquid to a clear, limpid, alkaline fluid which at times presents suspended floccules. Another method of value in determining this fact is the failure to withdraw any fluid swallowed, such as broth or milk. The so-called duodenal tug is obtained but rarely and cannot always be relied upon. The röntgen ray is the method *par excellence*, but for obvious reasons cannot always be employed. Recently Palefski suggested inflating air slowly through the tube and if it has passed into the jejunum the lower abdominal quadrant will become distended and tympanitic, and the patient will neither eructate nor complain of discomfort.

After being assured that the bulb has passed the pylorus, the tube is connected with an aspirating bottle and the duodenal secretion obtained. Under normal conditions the common duct sphincter is frequently found closed and then but little or no bile can be aspirated. Fifty c. c. of a warm sterile thirty-three and one third per cent. solution of magnesium sulphate is then injected into the duodenum. The duodenal tube is again connected with the aspirating bottle and the magnesium sulphate siphoned off. In a few moments bile mixed with the magnesium salt appears in the glass cannula inserted in the tube. At times it is necessary again to stimulate with half the amount of magnesium sulphate to secure a flow of bile. We have not infrequently restimulated with fifty c. c. of hot water or broth with unusually good effect. The first bile obtained is considered common duct bile, and requires from one to three minutes to collect, the amount varying from ten to twenty c. c. It is clear, light yellow in color, with but traces of mucus.

Suddenly a transition occurs, the bile becomes darker and more viscid. This is gallbladder bile and is collected in a separate receptacle, appearing normally in amounts of from thirty-five c. c. to ninety c. c. Soon a third change occurs, when a thinner yellow bile appears in the glass cannula, which is then drained into a third bottle; this is freshly secreted liver bile which occurs normally in amounts averaging about ten c. c. When the aspirated fluid returns clear, which occurs after a variable period of time, 250 c. c. of warm Ringer's solution is slowly injected into the intestine to wash out any of the injected material that may have escaped into the bowel. This plan is followed for diagnostic purposes, but in the subsequent treatments no attempt is ordinarily made to segregate the various specimens of bile. Before treatment is instituted it is well to investigate and eradicate thoroughly all foci of infection, such as the teeth, tonsils, and paranasal sinuses, and on the other hand it is of great importance to note that the source of the focal infection may be located in the gallbladder itself and that this method presents a means of thoroughly investigating this possible focus. Cultures are taken of the common duct, gallbladder and liver bile, before, during, and at the end of a course of treatment. In quite a number of instances among our cases, Dr. C. E. Simon has discovered pure cultures of streptococci and staphylococci which have largely disappeared in a number of instances after prolonged treatment. No attempts were made by us to use autogenous vaccines in the treatment of any of our patients.

Before applying this method in the diagnosis and treatment of biliary and duodenal lesions, a knowledge of the normal appearance of the bile and duodenal secretions is of primary importance. As has been pointed out, in the fasting state the common duct sphincter is normally closed and the duodenal content is free of bile. It is alkaline in reaction, pearly gray, fairly transparent, syrupy, and stringy in consistency, and contains a few suspected floccules. The bile flows intermittently quite like the secretion of urine into the bladder through the ureters. This characteristic feature is especially manifested when the freshly secreted liver bile is being collected. The bile as it is obtained through a duodenal tube under normal conditions undergoes certain definite changes in color and viscosity, according to Lyon, first from a light lemon to a golden yellow then to a deeper, richer, viscid, more syrupy golden yellow to dark brown, and finally to a uniformly light lemon yellow, thinner and less syrupy than either of the first two specimens. Microscopically, normal gallbladder bile is free from pus cells and contains a few epithelial cells, bile crystals and traces of mucus. Bacteriologically, no pathological organisms are observed. Chemically, the bile is alkaline in reaction and contains the biliary pigments—bilirubin and biliverdin; the biliary acids—glycocholic and taurocholic, cholesterol, lecithin, fats, etc.

The diagnosis, as Lyon describes it, is then developed around the direct study of the bile and the manner of its discharge, on the gross appearances of the several specimens—the quantity, color, consistency, viscosity, transparency, turbidity, floccula-

tions, mucus, etc.; the cytological examination—epithelium, whether bile stained, its source, pus cells, crystals, concretions, red blood corpuscles, inflammatory debris, mucus, bacteria; into the chemistry—lecithin, cholesterolin, calcium, pigments, effervescence on acidification, etc.; and into the bacteriology by culturation of each of the segregated samples of the bile.

Failure to obtain gallbladder bile after stimulation with magnesium sulphate indicates complete obstruction of the cystic duct either due to stones, adhesions, or pressure from without by a tumor. Failure to obtain the clear, lemon yellow bile or common duct bile is indicative of common duct obstruction. Of course, neither gallbladder nor common duct bile is obtained when the common duct is obstructed. In these cases it is interesting to note that frequently, by means of fractional analysis of the duodenal contents, the pancreatic ferments are markedly diminished or absent. A mucoid discharge, bile tinged with flakes of red blood corpuscles followed by a thin watery discharge, has been frequently observed by us in cases of partial obstruction of the common duct, while an excess of gallbladder bile, that is, over ninety c. c., is indicative of gallbladder stasis. A diagnostic measure, which we have observed in a fair proportion of cases and which is of considerable value, is the pain produced immediately upon the introduction of the magnesium sulphate solution which is much like a mild gallbladder attack and is analogous to the pain occurring in cases of strictured ureters or in Dietl's crises when fluids are instilled into the pelvis of the kidney. Inspissated mucous or tarry bile; extreme atony or atrophy of the gallbladder; absence of bile in the gallbladder, the contents consisting of calculi only, are other conditions in which the recovery of bile may be impossible even after stimulation.

The chemical investigation into the composition and physical properties of bile is yet in its infancy and it is very probable that in the future much additional light will be thrown on this subject whereby the diagnosis of biliary conditions will be materially aided.

We have also noted, as Lyon has pointed out, in some instances a sudden turbidity in a clear bile will develop during drainage, which is due to the sudden passage of acid into the duodenum. The same condition can be produced artificially by adding dilute hydrochloric acid to bile in a test tube. Lyon has also encountered clear bile in which an effervescence, as well as a turbidity, was produced on adding hydrochloric acid, similar to the reaction of acetic acid and calcium phosphate in the urine, and it has been suggested on this account by Lyon that "we may possibly be dealing with calcium phosphate stones, potential or formed in the gallbladder."

In our study of the three hundred and fifteen patients on whom biliary drainage was practised all were cases that presented gallbladder disturbances in some form or another. Of these there were thirty-one cases of cholelithiasis, fifteen of obstructive jaundice, one hundred and forty-nine of cholecystitis, and one hundred and twenty of biliary stasis due to gallbladder atony. The diagnosis in a number of these cases was verified by operation, but

the clinical manifestations in all were so distinctive, while the x ray and laboratory findings presented such corroborative evidence, that there could be but little doubt as to the correctness of the diagnosis.

CHOLELITHIASIS.

This method of examination was found of value as an aid in the diagnosis in a number of our thirty-one cases of cholelithiasis. A dark turbid bile containing numerous microorganisms, with large quantities of mucus and pus and an increase in the cellular elements, is indicative of the presence of an infected gallbladder, and when such signs are accompanied by paroxysmal attacks of pain radiating under the right costal arch toward the back they are of considerable value in the diagnosis of cholelithiasis. But little can be expected from this form of treatment as a means of cure in this disease; on the other hand, the method is of undoubted value following operations as a means of overcoming infection and thus acting as a preventive measure in the recurrence of gallstones. It also enables us to give relief from discomfort and even from pain which still remains following the removal of calculi.

OBSTRUCTIVE JAUNDICE.

Of our fifteen cases of obstructive jaundice, eight were instances of catarrhal jaundice and seven of obstructions due to other causes. The inability to obtain the gallbladder bile in these cases may be explained in one of several ways:

1. To a cystic duct obstruction in which repeated efforts may fail to obtain gallbladder bile and in which there is also often present a catarrh of the common duct.

2. To inspissated bile too thick and ropy to flow through the duct or in which the duct contains calculi causing obstruction to the flow. In the first of these conditions repeated daily drainage is likely, after a longer or shorter period of time, to be followed by a free flow of bile with the disappearance of the jaundice.

3. To pressure on the duct from without, as by tumors.

In cases of catarrhal jaundice our experience is entirely in accord with that of Lyon. The duration of the jaundice is lessened by this plan of treatment and recovery greatly hastened. In all of our cases the jaundice had entirely disappeared within ten days to two weeks. We have also observed in all of our cases of obstructive jaundice that by means of fractional examination of the duodenal contents the ferment values are markedly diminished.

CHRONIC CHOLECYSTITIS.

In our one hundred and forty-nine cases of chronic cholecystitis the most brilliant results were achieved by biliary drainage. This condition is demonstrated by obtaining gallbladder bile containing much mucus and a slight increase in leucocytes and with large numbers of microorganisms (streptococci, staphylococci, micrococcus catarrhalis, or colon bacilli) often in pure cultures. When the leucocytes are markedly increased in numbers and are largely of the polymorphonuclear type, the condition points to an acute stage of the infection which may pass into

the suppurative type and lead to an empyema. In cases of chronic cholecystitis our labors are frequently rewarded by noting a gradual reduction in the number of colonies of organisms as the treatment progresses, with marked improvement in the patient's condition.

BILIARY STASIS.

One hundred and twenty cases in our series were due to biliary stasis; these present an interesting group. Lyon has called attention to this condition and has pointed out that many cases of so-called biliousness are really instances of biliary stasis. The condition is due to an atony of the gallbladder, the degree of which may vary from a moderate weakness of the walls of the gallbladder to a stage in which the gallbladder is no longer able to discharge any of its contents. According to our experience the normal amount of gallbladder bile varies between thirty-five and ninety c. c.; an amount obtained over ninety c. c. is indicative of gallbladder stasis. In this condition the bile is ordinarily of the static variety; very thick, tarry in character, requiring usually many attempts before the gallbladder can be thoroughly cleared, and it is infected with many microorganisms. With daily treatments often extending over many weeks such cases can be greatly benefitted, the bile assuming after a time a more normal appearance, the microorganisms gradually decreasing in numbers, and the patient then presenting a marked improvement in his condition. It is quite probable that in many of these cases the formation of gallstones can be prevented by this form of treatment.

There is a large series of cases to which attention has already been drawn and which are grouped under the term biliousness. Such patients are sallow in appearance, weak, affected with indigestion and constipation, and are frequently the subjects of sick headaches and migraine attacks.

Our observations regarding this condition are entirely in accord with those of Lyon, that in many of such cases severe types of biliary stasis are observed due to atonic infected gallbladder. By means of biliary drainage it is not unusual to observe a rapid change in the appearance and strength of the patient and an improvement in the digestion and constipation, with complete relief from the acute attacks.

CASES EXAMINED.

The efficacy of this new procedure is well illustrated in the following two cases:

CASE I.—Mr. J. S., aged fifty-five, had his gallbladder drained and adhesions liberated in 1915, following years of indigestion and mild though typical gallbladder attacks. No stones were found. The patient was apparently well until four months ago, when attacks of colicky pain in the upper right abdomen reappeared. The x ray and bile examinations corroborated the diagnosis of an upper right quadrant affair. The patient reported for treatment and was perfectly willing to submit to a surgical procedure. After four weeks of daily bile drainage treatments the patient was dismissed entirely well, with the bile free of any infection. We have heard from this patient recently and he writes that he has

been perfectly well, but he still employs the duodenal tube every two weeks as a factor of safety.

CASE II.—Mrs. W. B. P., aged forty-three, had typhoid fever at the age of sixteen, and ten years later began to complain of acidity, gas, and fullness in the abdomen after eating. Shortly afterward, typical, severe gallbladder colic attacks appeared followed by jaundice. These attacks increased in severity and frequency until it was deemed advisable to operate. In March, 1917, Dr. Finney removed a gallbladder filled with stones. For one year there was complete relief, when the attacks of pain followed by jaundice reappeared. Dr. Charles H. Mayo made an exploration in the early part of 1918, and found a strictured common duct, due to adhesions. No stones were present. Then followed a period of absolute freedom from attacks for over a year when they reappeared identically the same but of increased severity, and for the past six weeks a protracted attack with jaundice and pain required the constant administration of morphine for relief. On account of her past operative procedures it was deemed advisable to institute non-surgical biliary drainage. After a few weeks' treatment the patient was also entirely relieved. At the present writing she is still employing the treatment at intervals of two weeks.

CONCLUSIONS.

1. The method of biliary drainage, as instituted by Lyon, furnishes a valuable aid in the diagnosis of gallbladder affection. It is particularly valuable in that it enables us to diagnose these conditions early before evidences of complications have manifested themselves.

2. It presents an important means of determining the presence of focal infection in the gallbladder, a condition which may be of the greatest therapeutic and diagnostic value in obscure conditions.

3. While this method of treatment is still in its infancy and is as yet too new to draw conclusions regarding its end results, there can be no question that it furnishes us with a means of affording definite relief in certain biliary affections for which hitherto radical measures have been required. It is an extremely valuable aid in the treatment of catarrhal jaundice, biliary stasis, and gallbladder infections, and is helpful in relieving the infection which may still remain following gallbladder operations.

BACTERIOLOGICAL STUDY.

The following bacteriological study was made by Dr. Charles E. Simon, of Baltimore.

Until very recently very little was known of the bacterial flora of the bile. It had been ascertained that in most if not all cases of typhoid fever typhoid bacilli appeared in the feces at some stage of the disease, and that these come more commonly from the gallbladder than from the intestinal ulcers. A certain degree of cholecystitis it was ascertained occurred in practically all cases of the disease and the persistent elimination of typhoid bacilli by fecal carriers was found to be due to a persistence of the infection of the gallbladder, which not infrequently was associated with the development of gallstones. These findings were based in part upon postmortem investigations and in part upon opera-

tive procedures which had been called for by the existence of stones.

PRESENCE OF COLON BACILLI.

Colon bacilli have also at times been encountered in the bile at autopsy, and, as Welch has shown, they occasionally occur in gallstones, which proves that the infection of the gallbladder with these organisms may take place *intra vitam* and is not necessarily a postmortem event.

In cases of acute cholecystitis streptococci and staphylococci have further been encountered at operation, but little attention has been paid to such observations. The various works on surgery and pathology up to the present time offer very little information indeed on the subject under consideration.

The systematic study of gallbladder infections has as a matter of fact been inaugurated only since Lyon called attention to the comparative ease with which bladder bile can be obtained through the duodenal tube, after stimulating the duodenal mucosa with magnesium sulphate.

FREQUENCY OF INFECTION.

The data which have been obtained in this short interval of time are very interesting from many points of view. They show very clearly that bacterial infections of the gallbladder are much more common than had hitherto been supposed, and that infections with pyogenic cocci are much more frequent than bacillary infections. Whatever the therapeutic value of nonsurgical drainage of the gallbladder may ultimately prove to be, so much is certain that as a method of diagnosis the bacteriological study of the bile has already assumed a position which must rank as equal in importance with other standard methods of examination. No search for foci of infection can hereafter be regarded as complete which does not include an examination of the bile.

METHOD OF PLATING.

It is not the purpose of the present paper to enter into a detailed discussion of the technic which is to be employed in the bacteriological study of the bile. It is merely intended to present in concise form the findings which were obtained in the course of a routine examination of seventy-eight specimens of bladder bile from forty-seven different individuals, such as they were received from Dr. Friedenwald's clinic. It may be mentioned, however, that in every case the specimens were plated out both on blood agar and upon Drigalski-Conradi's medium. This is absolutely essential. A mere examination of smears will furnish an altogether erroneous impression of the true situation. The latter method should never be employed alone.

BACTERIA FOUND.

No organisms of any kind were found on seventeen occasions. Saprophytes, for the most part spore bearers, were encountered thirty-one times; diphtheroids, twice; colon bacilli, six times; staphylococci, twenty-seven times, usually *Staphylococcus aureus*, on three occasions *Staphylococcus albus*; large gram negative side to side diplococci which were viewed as *Micrococcus catarrhalis* twice and hemolytic streptococci five times; on two occasions

capsulated diplococci were encountered, but not identified.

NUMBER OF COLONIES.

The number of colonies per c. c. of bile varied within wide limits, viz., between 100 and 750,000. In some cases a striking diminution was noted on successive examinations. In one instance the following figures were obtained:

November 27, 1920.....	12,500 organisms to the c. c.
December 15, 1920.....	6,250 organisms to the c. c.
January 13, 1921.....	9,000 organisms to the c. c.
February 4, 1921.....	0 organisms to the c. c.

In another case the figures were the following:

February 7, 1921.....	11,250 organisms to the c. c.
February 25, 1921.....	4,500 organisms to the c. c.
March 8, 1921.....	0 organisms to the c. c.

In other cases, on the other hand, no change was observed. Single infections were the exception. Leaving the saprophytic organisms out of consideration the findings were the following:

Staphylococci alone.....	11 times
Streptococci alone.....	15 times
Colon bacilli alone.....	2 times
Staphylococci together with streptococci.....	5 times
Staphylococci together with colon bacilli.....	2 times
Staphylococci, streptococci, and colon bacilli.....	2 times

Of special interest was one case, an old gallbladder infection, in which *Bacillus subtilis* was encountered again and again as the only organism that developed on the blood agar plates. At operation the same organism unaccompanied by any others was cultured directly from the gallbladder. Following the removal of the gallbladder the bile was found to be sterile on subsequent examinations.

ABSENCE OF TYPHOID ORGANISMS.

Typhoid bacilli were not found in any of the cases. But it is well to bear in mind that Bogart found that in typhoid carriers the organisms could be demonstrated much more readily and much more constantly in the bile than in the feces. In suspected cases this method of examination should always be employed when fecal examinations give negative results.

METHOD OF INFECTION.

It would, of course, be tempting to speculate upon the manner in which the gallbladder becomes infected in those cases in which no history of a severe systemic pyogenic infection can be elicited, whether the organisms gain entrance by way of the common duct or whether they reach their destination through the circulation. From the available data we are scarcely in a position to reach a conclusion. It would be interesting to conduct bacteriological blood examinations as a matter of routine in large series of cases of tonsillitis and so-called winter infections, to determine whether organisms do not pass through the circulation in these maladies, which are so commonly regarded as unimportant and which we are coming to look upon more and more as really serious. During those febrile flareups, which one meets so frequently in individuals with badly infected teeth, blood cultures would also seem to be indicated, and, as we have already pointed out, no search for pyogenic foci can hereafter be regarded as complete in which the condition of the bile has not been adequately investigated.

1013 N. CHARLES STREET.
1528 EUTAW PLACE.

Gastroenterological Gleanings from the Mayo, Sippy, and Boston Clinics*

By S. WENDKOS, M. D.,
Philadelphia.

Before my departure I had in mind certain definite problems on which I wanted light. Some of them were:

1. How to diagnose cancer early enough to be operable. 2. How to recognize with greater sureness ulcers of stomach and duodenum in the early stages, before perforation occurs, and before adhesions and deformities have taken place. 3. How to differentiate more definitely the symptomatology of organic disease from functional disturbance. I also wanted to get a clearer conception of functional disease, or so-called neuroses, one sees so much of, and so frequently mistakes for organic trouble.

THE MAYO CLINIC.

To solve one or all of these problems I betook myself to America's medical Mecca, the Mayo Clinic at Rochester. I arrived there on a Saturday afternoon, and on my way from the station I inquired of the taxi driver where St. Mary's Hospital was, thinking that was where the Mayo Clinic could be located. I was informed that it was two miles away from my hotel, so decided to wait until Monday to visit the clinic. Late in the afternoon, while walking out to see the town and before I had gone more than a few steps from the hotel, I saw people coming from every direction toward the hotel. I walked around the corner and looking up at the front entrance of an imposing building, I saw the inscription Mayo Clinic. I stopped in amazement and watched the people going in. There were hundreds; old and young, on foot and in wheel chairs, lame and straight. Many had dressings around their necks and many others carried bundles under their arms, the bundles happening to be gallon bottles wrapped up neatly and containing urine (twenty-four hour specimens). For many minutes I stood and watched the crowd. It was Saturday, when the Clinic is usually closed, but since it was the fifth of July and the Clinic had been closed on the Fourth, it was impossible to close it an extra half day. That was the reason so many people rushed to the place for examination, advice, or treatment.

To the newcomer it was a sight not easily forgotten, and it would require the pen of an artist like Zola, who described similar scenes at the French Grotto at Lourdes, to do this scene justice.

I walked in, following the crowd, and saw an immense waiting room, more like the beautiful foyer of a hotel than a waiting room in a hospital, in which hundreds of patients were waiting. Upon inquiry, I learned that about three hundred new patients register daily. When I presented my letter of introduction from Dr. John B. Deaver, I was cordially received by Dr. Eusterman, chief of the gastroenterological department. I told him my

mission, and the first thing he did was to take me up to their splendid library and gave me to read the introductory chapter of the *Oxford Loose-Leaf Medicine*, by Dr. MacKenzie. Weeks later I realized the significance of that act. Those of you who read abstracts of Dr. MacKenzie's papers or addresses while he was in this country recently will remember that he evolved a new philosophy of medicine, distinct from the German conception which prevailed hitherto. I shall not enter into this at present; suffice it to say, that the main principle is the recognition of the diseased condition, not by signs and symptoms derived from gross pathology and the postmortem room, but by functional disturbances which precede gross pathology. In other words, we should endeavor to recognize conditions in their incipiency. The spirit pervading the article is that of rugged common sense and sane conservatism. The same spirit I found pervading the Mayo Clinic.

Fully half their patients are sufferers from gastroenterological disease. All are given a thorough physical and routine laboratory examination, including uranalysis, blood tests. (very frequently a Wassermann), chemical analysis of the gastric secretion, and x ray examinations. For the past six months only, they have used the fractional method of gastric analysis, but in a modified form on account of lack of time; instead of every fifteen minutes as Rehfuess directs the secretions should be extracted, they do it every forty minutes for three specimens. Before the tube is removed a test is made of the acidity. If achylia is present then the tube remains longer and more specimens are withdrawn. However, if acid is present in the first three specimens, the remains of the test meal are withdrawn until the stomach is empty. If 200 c.c. are recovered, it speaks for retention. This is strengthened by the fact that on examining this residue, bits of raisins and rice are found. These facts are carefully noted on history charts; the patient is then referred to the x ray laboratory.

All such cases are fluoroscoped and plated. Fluoroscopy is done by Carman himself. From fifty to sixty patients are referred to him every afternoon. He works rapidly and his vast experience enables him to see in a flash what it would take others many minutes to see. The element of time is here also a great factor. He cannot wait to observe the normal action of each particular stomach, but by quickly forcing the barium into the duodenum, it becomes distended and better visualized, and the outline can be seen either clearly defined or deformed. If the latter, it indicates, of course, organic disease. Only fifteen per cent. of the cases sent to him are diagnosed as organic in nature with a definite pathology. Now, remembering that all the cases are special cases, the patients coming from

*Read before the Mt. Sinai Hospital Clinical Society, Philadelphia.

afar, not only highly neurotic city bred individuals, but the majority farmers, ranchers, and country people, I questioned in my mind about the remaining eighty-five per cent. The fifteen per cent. with organic disease represent the far advanced cases, with marked pathological development, for which there is hardly a need for the x ray. I expected to see this important laboratory procedure of service in less marked cases. Assuming that fifty per cent. of the cases were sent as a matter of routine, there still remained thirty-five per cent. which presented definite clinical signs and might have been overlooked for lack of time to study them. I have seen patients brought to the operating room and a diagnosis of duodenal ulcer made, but upon exploration several gastric ulcers were found and these had been missed by the x ray.

Fluoroscopic examination is considered at this clinic of the greatest importance. Plates are made simply to demonstrate the lesion and sometimes to bring out doubtful points which do not clearly show on fluoroscopy. A definite diagnosis is based, first, on the x ray; second, on the history, and third, on chemistry. On rare occasions, however, when the x ray is negative and the history suggestive of ulcer, the order is reversed. In my judgment history should always be first, provided one knows how to elicit a proper history; the x ray should be second, and chemistry third. The evidence of this trinity should always be taken together.

During operation, the Mayos philosophize on the relation between ulcers and cancers, their etiology, treatment, and the relative merits of medical and surgical treatment. Very often, they take a fling at the medical man, and Sippy, the exponent of medical treatment, comes in for sarcastic remarks. The Mayos, of course, uphold the surgical treatment of gastric and duodenal lesions. The younger men, however, do not share this extreme view, but admit that certain cases are amenable to medical procedures. In a recent article, the Mayos even advise a reasonable medical cure before surgery is resorted to. This feeling is widespread now even among surgeons. I was watching the examination of a patient by Dr. Eusterman, when he turned to me and said, "Sometimes we are compelled to make a diagnosis for geographical reasons," and he showed me a man who came from Alaska, complaining of pain in the right quadrant. Localization was not definite, but nevertheless, a diagnosis of subacute appendicitis was made and an operation ordered, simply because the patient lived too far away from a reputable surgeon. If he had lived nearer, he would have been sent home for the further development of more severe symptoms and a more definite pathology. At operation, however, a large stone was found in the gallbladder, which undoubtedly accounted for his symptoms.

I have dwelt so far on the diagnostic and medical sides of my observations and have not said a word concerning the surgical aspect, the reason being that I am not competent, since I am not a surgeon. However, my opinion as a medical man is that their surgery, technically speaking, is superb. They believe in large incisions, and they believe in seeing what they are doing. The importance of this,

I leave to the surgeons to discuss. Their work, no matter how complicated a condition may be found, seems comparatively easy to the onlooker. On the other hand, I have seen a surgeon in Chicago do a gallbladder operation through a small incision, and he literally sweated blood.

All the stomach cancers I have seen operated upon were inoperable. This was very discouraging to me. I thought to myself that the patients either arrived too late, or the diagnosis was delayed too long for definite and classical symptoms. I have seen a man there with a history of pain, some loss of weight, and a slight degree of dilatation and retention, as shown by the x ray and gastric findings. Yet, he was sent away for six months after which time he was to return and report on his condition. Suppose he had an incipient cancer which was operable, in six months becoming inoperable? I saw another patient opened up for inoperable cancer who had been in the clinic a year previous to operation, but who could not stay longer for observation and perhaps operation. Dr. Mayo told us that surely the man must have shown symptoms of cancer and if he had been impressed with its seriousness he would certainly have submitted to surgical treatment. On the other hand, they do wonderful work in intestinal cancer. The slightest pain in the abdomen with mucous or bloody stool is thoroughly investigated by proctoscopic and sigmoidoscopic examination, as well as x ray, and thus they are able to discover the earliest manifestation of malignant changes. Wonderful results follow their resections.

In mentioning some of their errors, as I have done, I do not wish in the least to depreciate the Clinic in any way; I simply desire to point them out as human errors, which are inevitable as a part of so much clinical material and so much excellent work which may depend on extraneous factors, such as economy of time, lack of sufficient space where patients may be observed for a longer time, and perhaps lack of sufficient medical help.

My method of observation was entirely original. Many patients were registered at my hotel while they were undergoing examination, and as all patients like to talk, I had no difficulty in eliciting a history of their complaint. When I told them my reason for being in Rochester, they were pleased that I took an interest in them. In this manner I was able to follow up many patients from clinic to operating room.

Usually physicians go to the operating room and look on the procedures which are well nigh perfect and very interesting to the surgeon. As I was not much interested in the surgical technic, but more in diagnosis, I had to be shown the why and wherefore, and so I looked for it. I read histories, looked at charts, and wanted to know the reason for operation. In this way I came across many curious and interesting conditions. One day I came into the operating room where a patient, already under ether, was being prepared for operation for varicose veins. Her legs were exposed preparatory to the application of iodine and I looked again and again, but could not see any varicosities. Well, I thought to myself, they might perhaps be collapsed;

but, yet, one should see their tortuous course. The patient was a big woman, "fat and forty," from South America, I believe. I walked over to the wall where the charts were and read some of the history. In brief it was as follows: Chief complaint, bearing down pain. The patient had had varicose veins, but there was also a history of gastric distress with jaundice several times. Patient vomited bile, had sour stomach, and was bloated after meals. Tenderness under right costal margin was present. Now you all know what Dr. Deaver would have operated upon this patient for, and yet the simple operation for varicose veins was performed. Can Dr. Deaver blame the medical man alone for procrastination in gallbladder surgery?

Another case that interested me greatly was that of a man of fifty, who was operated on for the removal of an impalpable and invisible thyroid, for the only reason that he had a persistent tachycardia and a high basal metabolism, which was plus forty-five; and this to them indicated a thyrotoxic condition. The operation was performed to save his heart from further myocardial damage. No such patient would have been operated upon here. Their immense experience in thyroid surgery entitles them to our confidence in their better judgment.

Fully half of my time I spent in their splendid library, which was a beehive of activity. Here one meets the chiefs pouring over some old periodicals, or the younger men engaged in research on problems assigned to them, or visiting physicians who wish to supplement their observations by reading. Here I read Dr. Deaver's paper on gallbladder pathology, where he blames the medical man for not recognizing gallbladder disease early enough. I carefully read and digested the original papers of the Mayo staff and assistants, regarding the etiology, pathology and bacteriology of gastric and duodenal ulcers.

As you know, Rosenau isolated a specific streptococcus causing ulcers of stomach and duodenum. He was able to reproduce these ulcers in the stomach by the injection of certain types of streptococci. Luigi Durante, of the clinic, experimentally produced gastric lesions through the artificial perversion of the nerve supply of the stomach and the duodenum. F. C. Mann made a study of gastric ulcers which followed the removal of the adrenals, and so I have learned that a real, chronic or mucous ulcer may begin as a neurosis due to faulty innervation and failure of certain internal secretions, or to fatigue or degeneration of the nerve fibres supplying the mucosa of the gastric and intestinal tract. A potential ulcer may then masquerade as a neurosis for a long time.

THE SIPPY METHOD.

Next, I went to Chicago to study the Sippy method of medical treatment of ulcer. His influence over the Chicago medical profession is apparently so great that during my stay of nearly two weeks I did not see one operation for ulcer listed on the surgical bulletin. I was pleasantly surprised to find that he does not lay claim to an ulcer cure, but terms his method ulcer management. I think credit is due to him for the very fact that he im-

pressed the medical profession that ulcers must be managed by strict régime, even as diabetes or Bright's disease was for a long time. He keeps his patients from two to four weeks in the hospital and plays with them to get the "dope," as one of his assistants expressed it to me, by a system of gastric aspirations, such as, 1, secretory; 2, therapeutic; 3, control; 4, motor aspiration. If patients are not benefited by alkalinization, he doubts the existence of an ulcer. If relief results from an enema, he suspects intestinal irritation as the cause of the stomach symptoms. The enema is also a diagnostic procedure with him. It is given a quart at a time at short intervals. If by gradual distention of the intestines pain is aroused, and when expelled pain disappears, then the condition might be intestinal. If no effect is produced by the enema, then the pain is gastric in origin.

Sippy has elaborated a complex system of dietetic treatment for gastric and intestinal conditions, especially ulcers. He starts his ulcer management by giving half of a glass of sweet cream and milk every two hours, and a powder of calcium carbonate or magnesium oxide in combination with sodium bicarbonate. The cream and the powders alternate. This is kept up for four days. On the fifth day one feeding is added and consists of an egg. The non-milk feedings are increased to six a day, and they comprise nonirritating and bland foods, rich in fat and protein. The increased fat in the stomach coats the gastric mucosa and thus lessens irritation. His belief is that the acid secretion is the cause of the pain.

Chronic diarrhea is often treated by diet, but I have noticed on Sippy's charts that opium is frequently used in this condition, so the formed stools cannot be due to his diet alone, which he asserts to be the case. In my opinion his claims are greatly exaggerated and when it comes to treating gastric ulcers, real or even suspected, he is playing with fire, since in thirty per cent. of these cases cancer develops. When it comes to treating women with gastric disturbance, the control of the hyperchlorhydria assumes an importance out of all proportion to its real significance as the cause of the condition, forgetting that it may be a concomitant symptom of gallstones or pelvic disease, which surgery alone can cure. Sippy's aversion to abdominal surgery has come at the psychological moment when surgery has begun to take stock of its afterresults and has found a great gap. What physician does not know of cases in which the patients have been operated upon without relief from the symptoms that led to operation? How many have been operated upon on x ray evidence alone and no lesion found? So there arose scepticism, in both laity and medical profession as to surgery's infallibility in this field. Sippy swung the pendulum to the other extreme, asserting that all ulcers should be treated medically. He is taking advantage of the present state of incredulity existing in the public and, to use the slang expression, "is cleaning up" in Chicago and the territory it drains. Furthermore, he does not believe in the newer advances in diagnostic procedure; he relegates even the x ray to a far removed seat; he uses it only for confirmative purposes, so when there

is nothing to confirm, he does not employ it; and yet his cases with epigastric pain pass for ulcer. The Chicago profession swallows his claims, which Philadelphia would not, I am sure.

BATTLE CREEK SANITARIUM.

From Chicago I went to the Battle Creek Sanitarium. This institution has my greatest respect. It stands between Rochester and Chicago, embodying the spirit of scientific investigation and research and thorough diagnosis and the belief in systematic, prolonged, dietetic, and physical treatment as necessities to a cure. My detailed observations I shall reserve for another occasion in a separate paper.

BOSTON CLINICS.

Boston clinics were my last destination, the two institutions that claimed my attention being the Massachusetts General Hospital and the Peter Bent Brigham Hospital. At the latter institution I found a gastrointestinal clinic conducted by Dr. McClure, who was treating his patients with psychotherapy. In Chicago, or elsewhere, this would have surprised me, but in Boston, the home of American religious mysticism, philosophy, psychology and the Emmanuel movement, such a clinic was a logical conclusion, and it interested me greatly. In a conversation with Dr. McClure I asked him the reason for such a clinic. He answered that he was doing it for experimental purposes. The gastrointestinal disturbances are so many and the correct diagnosis so difficult that he was endeavoring clinically to sift and separate them into distinct groups. Furthermore, he was trying to find out what part physical and nervous fatigue, as well as mental strain, played in the production of gastric symptoms. In so many cases patients had been operated upon for chronic appendicitis and even for ulcer with no relief, that he was desirous of finding the reason. "What if the nervous manifestation merely masks an organic lesion?" I asked him. "We do not lose sight of this possibility," he answered. "All that we do is to try to restore the patient's confidence in his own stomach by assuring him, after a careful physical examination, that there is nothing wrong and instruct him to eat plenty of nourishing food and at the same time to build up his morale. We believe we relieve him of his worry; if fatigued, we send him to a convalescent home; if he has financial and family friction, we send a social worker to smooth them out; if he has bad teeth, we urge him to have them attended to. In this way we succeed in building up the individual and curing him of gastric trouble." While this clinic has been conducted only six months, many patients have been restored to normal digestive activity.

In the general medical clinic I have seen many patients who gave as their chief complaint gastric symptoms of various degrees of severity, but after routine examination many were found suffering from tuberculosis, heart disease, or other nongastric conditions. A good gastroenterologist must indeed be a first class internist.

Dr. Shmookler used to maintain that the only gastroenterologist in existence was the surgeon; of course, he meant Dr. Deaver, who used to lay bare the living gastric pathology and upon the re-

moval of either an ulcer or a cholecystitis the symptoms would usually disappear, at least for the time. I hope that both of them think differently now. I know that Dr. Shmookler and Dr. Deaver, and others as well, have patients on their hands who have undergone several surgical cures and still complain of the original symptoms. So you see, some patient do not get well even after surgery has tried its sure method.

In the past, except in cases of acute ulcer, there was no rational medical treatment for the chronic types, because we had no rational conception of the underlying factors. Our first real knowledge indeed came from the surgeon, but the application by the thoughtful physician of this knowledge made the subject much clearer to us than it had been formerly. Moynihan's classification of the symptomology was a great help, but when carelessly applied met with many failures, so much so that surgeons were afraid to make a definite diagnosis and the era of explorations held sway. The x ray then came to their assistance and aided considerably in localizing the various gastric lesions actually seen by the radiographer. But when Holzkecht came out with his ulcer syndrome of hyperperistalsis, delayed motility meant ulcer, and the result was the same as that which followed the symptom complex of Moynihan.

CONCLUSIONS.

To sum up, from the different modes of thought regarding the etiology, psychology, pathology, diagnosis, and treatment of gastric disease, I formed one composite conception, for myself, of this most difficult branch of internal medicine. It consists of the most widely prevailing opinion, that as regards organic disease of the stomach and its adnexa, infection and intoxication play the most important rôle; that infection takes place as a result of infections in the mouth, respiratory tract, appendix and elsewhere, as primary foci; that the seat of intoxication is in stasis of the intestinal tract; that disturbances of the autonomic nervous system produce many gastric conditions, simulating organic disease; that the diagnosis should be based on a thorough study of the individual from the points of view outlined above, and of the intestinal tract, including detailed history, physical examination, x ray, and, last but not least, chemical examination of the secretions; that medical treatment properly applied, even in organic disease, is more efficient in early cases than surgery; that chronicity of ulcers is produced by lack of proper treatment in early stages; when properly managed by dietetic régime and frequently gauged by the fluoroscopic screen, the degree of improvement can be studied to better advantage. I believe that by following such a program many more cases can be cured medically, more cases brought to the surgeon much earlier, and thus will be diminished the incidence of cancer implantation, and the surgical complications arising from myocarditis, arteriosclerosis, and other conditions when operation is delayed too long. I believe that the newer type of gastroenterologist is to be commended for selecting the most difficult branch of medicine.

1527 NORTH FRANKLIN STREET.

Some Interesting Gastric Cases

By HENRY FLACK GRAHAM, M. D., F. A. C. S.,
Brooklyn, N. Y.

The argument over medical versus surgical treatment for gastric disorders is an ancient one. Frequently the problem is a hard one to solve correctly, but I think no one will dispute the fact that surgery alone could have given relief in the series of cases herewith reported. They illustrate a number of different conditions that have purposely been abbreviated as much as possible.

The operation used in most of the ulcer cases consisted of excision of the pylorus of the stomach and adjacent duodenum, closing up the end of the duodenum and uniting the open end of the stomach to the jejunum through an opening in the transverse mesocolon. The portion of jejunum used was about four inches from the duodenojejunal junction.

CARCINOMA OF THE STOMACH.

CASE I.—J. J., female, aged thirty-nine years. Six years ago, after the birth of a baby, she began to feel tired. For the past seven months she had regurgitated her food, often immediately after eating and sometimes at night. She had no pain except immediately before vomiting, and the vomiting relieved it. She had never vomited blood and had lost only four pounds in the last six years. Examination showed a thin, emaciated woman of sandy complexion. The teeth were very bad. The abdomen was thin and spastic and there was a sensation of mass in the epigastrium. The x ray showed considerable six hour residue. A diagnosis of pyloric obstruction was made and operation was performed at the Norwegian Hospital, August 23, 1920.

The entire pylorus was the sight of a hard nodular mass measuring two inches by five inches, infiltrating the wall of the stomach and gradually shading off into the normal stomach without any sharp border. The pylorus and adjacent two thirds of the stomach were resected. A posterior no loop anastomosis was made with the jejunum. The time of operation was two hours. Microscopical report on the section removed was carcinoma.

This patient vomited off and on for the entire day following operation. The interns were afraid to perform lavage and so let it go. After lavage, however, she vomited only once during her entire stay in the hospital and that was only three ounces. She received over two hundred ounces of fluid by rectum and under the skin. Our rule now is that a lavage shall be done after the first vomiting that occurs later than the anesthetic vomiting.

When seen two months later she weighed the same as before her operation, was feeling better daily, and gaining weight, she thought. On January 6, 1921, she was again seen. She had no pain and felt the best she had in ten years. She had three children and did all her own work, including washing. Three pieces of bread and a glass of milk filled the stomach. There was no sign of recurrence. On February 26, 1921, she had distention of the lower abdomen and a sense of mass in that region. The

epigastrium was soft, and no masses were present there. Evidently a recurrence was taking place at some distance from the site of operation.

CALLOUS ULCER OF THE STOMACH (PYLORUS).

CASE II.—S. H., female, aged thirty-seven years. This patient had had indigestion for twenty years with periodical attacks of pain in the epigastrium. She rarely vomited. The attacks would last for several weeks. The pain came on several hours (three or four) after eating and radiated through to the back. It was relieved by eating. She was always hungry. On January 13, 1920, she vomited a large amount of blood and was taken to a hospital in an ambulance. Since 1917 the suffering had increased, the attacks had become more frequent, and there had been more vomiting. She vomited food twenty-four hours after eating it.

Examination disclosed a hard, tender mass the size of a golf ball in the epigastrium. Her weight at that time was about seventy-nine pounds. She was much emaciated and had been in three other hospitals for treatment. Operation was performed at the Norwegian Hospital on June 23, 1920. A mass was found at the upper and posterior portion of the pylorus which was adherent to the abdominal wall anteriorly and to the pancreas posteriorly. The latter formed the bed of the ulcer. A pylorotomy was done and a portion of the head of the pancreas shaved off, or Pólya's operation, as in the previous case. Time of operation one hour and fifty minutes. The microscopical report gave no evidence of malignancy. She vomited three times during the first twenty-four hours, was lavaged once, and received about two hundred ounces of fluid by rectum and skin in the first few days.

After leaving the hospital she was troubled by cardiospasm. A stomach tube caught at the cardia but after a couple of minutes the spasm relaxed and allowed it to enter. On August 8th, seven weeks after operation, she had gained twenty-three pounds. A letter received January 8, 1921, said: "I was on seven machines and the average weight was 120 pounds. In March I was down to seventy-nine pounds. As regards pain I have none. I feel strong and very well indeed. It is a long, long time since I enjoyed such healthy days. I can do all my housework, washing, ironing, etc." Then follows a long description of the attacks of pylorospasm which still interfere, at times, with her eating.

I have ordered gradual dilatation with olivary esophageal bougies for this patient. She lives in Pennsylvania and it is difficult to carry on any proper line of treatment.

CARCINOMA IN THE EDGE OF A CALLOUS ULCER.

CASE III.—E. S., male, aged fifty-four. He had had pain in the chest for two years. It was not increased on inspiration and sometimes shifted to the back and right shoulder blade. Meat caused the pain two or three hours after eating and taking food

relieved it. He seldom vomited and the vomitus was clear sour water only, never blood. There had been three or four attacks in two years, each attack lasting two or three weeks. The present attack had lasted four weeks. This patient was given an ulcer diet and alkalis. He gained two pounds and a half

suture line had pulled completely out of the wall of the gut. The gastrojejunal opening now seemed rather too small. Diagnosis, peritonitis and lack of repair.

As an example of the tremendous amount of work entailed in the care of some of these cases: This patient received twelve hypodermoclyses of 335 ounces in all; 350 ounces of fluid were given by rectum, making a total fluid intake of 685 ounces. There were seventeen gastric lavages.

PERFORATED DUODENAL ULCER.

CASE IV.—J. C., male, aged twenty-two years; sheet metal worker. This patient had suffered in the past from acid eructations and indigestion. He once weighed 178 pounds. On August 6, 1918, he was operated upon for a perforated ulcer by Dr. Parker at St. Mary's Hospital. The perforation was closed but a gastroenterostomy was not done. Following this operation he was well for some months.

Six months previous to admission to the hospital he began to have a stabbing pain in the epigastrium which radiated up to the chest. It usually came two or three hours after eating and was relieved by eating. A severe attack at Christmas time lasted two or three weeks. He vomited nearly every day. Last March he vomited nearly a half pint of blood and also in May a smaller quantity. There were frequent white burning eructations. He was not constipated. He stopped work two months ago. X ray examination showed a dilated stomach. After entering the hospital the patient vomited three times before operation.

Operation was performed at the Norwegian Hospital on July 28, 1920; time one hour and forty minutes. A mass the size of a golf ball was found in the first part of the duodenum. Dense adhesions were all about. It was adherent to the liver and the pancreas and had ulcerated through into both

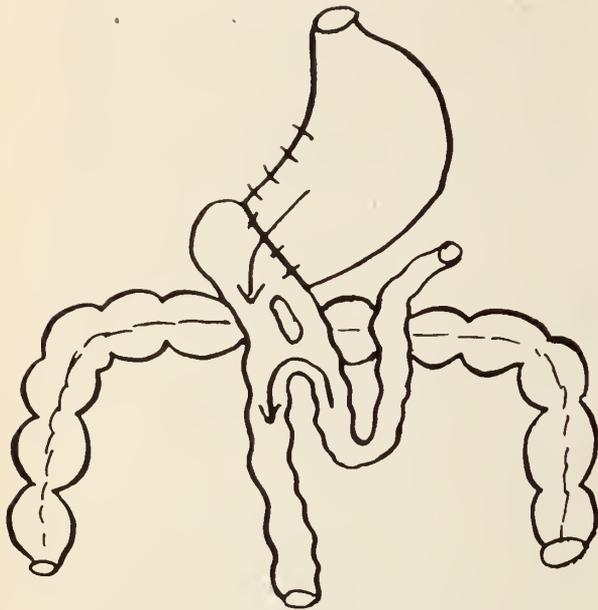

FIG. 1.—Anterior long loop operation with enteroenterostomy.

in a month and at times had no pain, but later became worse again and was sent to the Methodist Episcopal Hospital. An x ray examination showed bismuth in the stomach twenty-four hours after the meal.

Operation was performed on December 23, 1920, time consumed one hour and forty-five minutes. The posterior wall of the stomach and the duodenum were found very adherent to the pancreas. There was a hard ulcer the size of a half dollar on the posterior wall near the lesser curvature. As the stomach was loosened up behind and separated from the pancreas it left a round hole in the stomach wall and a large round ulcer base in the pancreas. (Microscopical report of the edge of this ulcer was carcinoma.) The ulcer was cauterized and the pyloric half of the stomach resected. An anterior long loop anastomosis with the jejunum was made and a jejunojejunosomy with a Murphy button.

There was considerable vomiting following operation and on the fifth day it seemed advisable to explore again. The button was loose and was removed and the anastomosis, which showed practically no sign of union, was sutured with two layers of suture material. The gastroenterostomy seemed freely patent and the suture line there was intact. The patient was given powdered charcoal which appeared in the stools. Lavage reduced the six hour gastric retention from twenty ounces to six ounces. Milk was given through the stomach tube and seemingly passed down through the intestines. Death, however, ensued.

At autopsy it was found that practically no repair had taken place in the closed end of the duodenum or at either anastomosis; both were easily pulled apart. There was some peritonitis where the last

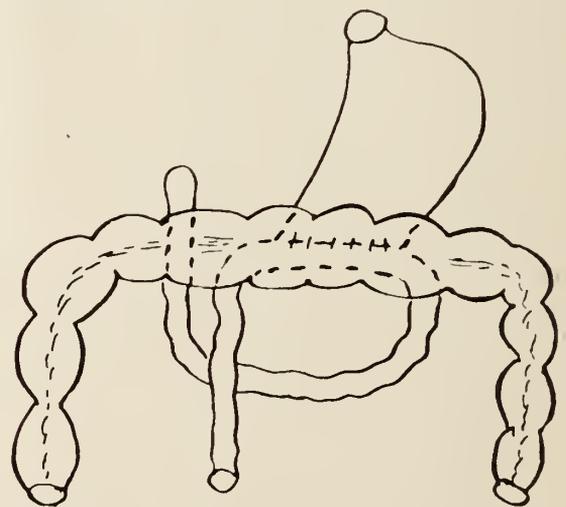

FIG. 2.—Posterior no loop operation.

leaving a crater. A pylorotomy, with a posterior no loop anastomosis to the jejunum, was done. The pancreas was sutured. Convalescence was very stormy. The patient returned from the operating room with a pulse of 160. Lavage on the second day was clear. On the succeeding four days there

were eight more lavages, then there was an intermission. On the ninth day bile appeared in the wound and a diagnosis of duodenal fistula was made. Pancreatic juice was present and excoriated the skin for an area of six inches in all directions. The petrolatum gauze used with Dakin's solution gave the most relief from this.

On the eleventh day he vomited again and was lavaged twice. On the thirteenth day he expectorated bright red blood, his respirations were labored, he was irrational and weak. By the fourteenth day the pulse was thready and his hands were cold and clammy. The relatives were notified and death seemed imminent. A surgeon, who saw him at this time as he was walking through the ward, remarked later, "I wouldn't have given you ten cents for him." He had received fourteen lavages. Much saline, glucose and sodium bicarbonate had been given by rectum and by many hypodermoclyses. We felt for these fourteen days as though we were sitting on a red hot griddle. Now the tide turned and the remainder of his stay in the hospital, thirty-eight days in all, was uneventful.

On October 4th I saw him and he was eating everything except meat and soups. His bowels moved regularly once or twice a day. There was no pain, and very little gas. On January 10, 1921, his weight was 151 pounds. He looked fine and healthy, color was splendid. He had gained twenty-five pounds since leaving the hospital, and was eating a little meat. Bowels moved once daily. He had no pain at all and no acid eructations. He was eating regular meals. The abdominal scar was firm; there was no ventral hernia.

DUODENAL ABSCESS.

CASE V.—O. E. H., aged thirty-two years, machinist. He had had attacks of indigestion from the age of twelve years. During an acute attack in 1909 he was taken to a hospital and his appendix was removed, without improvement of the condition. He had had severe headaches and vomiting spells at intervals of two or three weeks. On a trip to Norway in 1913 he noticed blood in his stool.

Operation was advised at that time and refused. He had been careful of his diet ever since.

In the spring of 1920 he began to lose weight and look paler, and there was a sharp expression in the eyes. On August 3, 1920, after eating herring and tomato which had been in the ice box three days, he went into convulsions which lasted two hours (perforation?). There remained a soreness in the right upper abdomen so painful that the patient could not move in bed. Five days later he entered the Norwegian Hospital. Some tenderness and rigidity were present over the duodenal region. There was a high differential and leucocyte count.

Operation was performed on August 18, 1920. An abscess containing four ounces of thick yellow pus was found occupying the region bounded by the pylorus, duodenum and gallbladder. The abscess was drained and the patient made a good recovery. Later reports indicated that he might possibly be cured although he had had one attack of indigestion from an indiscretion in diet. I would have done a gastroenterostomy in this case but it seemed inadvisable with pus present.

In conclusion let me make a plea for the surgeon who handles these cases. This is glorified plumbing, the hardest kind of surgery. It requires the greatest skill at the table and the utmost persistence and judgment afterward. And even if the work is all done properly there are still other factors to be reckoned with that may cause a fatal outcome. I know that the results in many of these cases are far from perfect but many a human machine has been taken from the junk heap and made to run again once more when there seemed to be no possibility of it. We cannot "restore again the years that the locusts have eaten," as the *Bible* puts it, nor can we make them all strong, healthy and free from symptoms, but we can get them back to work and useful members of society once more. Only one word in regard to aftercare. Frequent small meals of soft material; no meat or meat soups or condiments, and keep them away from work and worry as long as possible.

A Report of Some Abdominal Cases*

By VERTNER KENERSON, M. D.,
Buffalo, N. Y.

About six years ago one of two young men, who were out at the Buffalo city line practising with a rifle, had the misfortune to shoot the other in the abdomen, causing a penetrating wound of the small intestines, the bullet puncturing the gut seven times and passing out of the abdomen at the opposite side from that at which it entered. I was on service at the Erie County Hospital and was summoned at once. The young man was in a state of collapse, was bathed in cold perspiration, with weak pulse, and in poor condition generally. The intestines were full to overflowing with partly digested food.

I took with me two books of a dozen each of Lem-

bert silk sutures, which were already sterilized, and had them resterilized at the hospital after I arrived there. These books are simply pieces of cotton cloth, on which have been arranged twelve fine cambric needles, threaded with fine white surgical silk, and drawn into the cloth so that they will be readily available, and drawn out by simply taking hold of the needle and drawing, so that they will not be snarled when withdrawn. The silk in each needle is tied to the eye of the needle so that as little inconvenience as possible will result during the operation. These needles are so fine that it takes considerable time and patience to thread them, and there must be a supply sufficient for any given case al-

*Read before the Buffalo Medical Society, February, 1921.

ways ready, and in this case two books were taken and resterilized by boiling with the instruments at the hospital after my arrival there.

No attempt was made to evacuate either the bowel or the stomach. The exterior of the abdomen was cleaned as carefully as possible, shaved, and scrubbed with green soap, turpentine, and alcohol. An incision was started at the point of entrance of the bullet, and carried down to the peritoneal cavity. This at first was made about three inches along the line that the bullet was supposed to take, indicated by its direction from entrance to exit. When the peritoneal cavity was opened all extraneous matter was sponged out, the immediate surrounding viscera were sponged off, and the intestines examined without unnecessary handling.

Immediately below the bullet hole in the body wall I found the first hole in the small intestine, and this was pulled out ever so gently, walled off by laparotomy sponges, and repaired. Without trimming the ragged hole in the least, but simply inverting the edges into the wound, a double row of sutures were used to close each one in turn. The first row of Lembert sutures were placed close to the wound, passing the fine straight needle through the serous and muscular coats, but being careful not to penetrate the mucous coat.

The second reinforcing row of sutures was placed parallel to the first row but a little removed so that they were folded into the first row. No attempt was made to roughen the serous surface to make the stitches hold better, but the serous surfaces were coaptated as carefully as possible, and a double row of sutures used to make a tight seal. This turning in of the gut, using the second row to seal the first, was applied so that the pucker in the gut came in the length and not the circumference of the gut. In only one instance was there a hole on directly opposite sides of the same inch in length of the gut, and there was so much puckering that I thought there might be some loss of peristalsis and consequent occlusion. None developed, however, only some sluggishness, which was to be expected, especially after the administration of opiates. The little bleeding spots on the serous surface of the gut were simply turned in, if at or near the bullet hole, or simply tied in with a separate Lembert tie, if at a distance; no ties of catgut were used. There was little outside bleeding, and when Lembert ties were necessary, great care was used not to penetrate the mucous coat, as the silk suture is left *in situ*, and would act as a constant drain if infection followed from the site of the suture to the mucous canal.

After each bullet hole had been closed with this double row of Lembert sutures, as described, the surrounding tissues were sponged with normal sterile salt solutions, some being poured on the surrounding abdominal tissues, and the uninjured gut was sponged off as carefully as the circumstances would permit. The gut was then examined inch by inch and as soon as the next penetrating wound was encountered, steps were immediately taken to wall off that section of gut so that as little contamination as possible would be spread. This second hole was then repaired in the same manner as

the first, namely, with one row of sutures close to the bullet hole and a second reinforcing the first. In its turn the immediate surroundings were cleansed, the packing removed, and the wound left as dry as feasible and the exploration continued.

I did not make any attempt at first to determine how many holes there were, but simply repaired each one as fast as it was found. There was little bleeding except from the individual bullet wounds in the gut, and after seven had been repaired, exploration was made in the back of the abdomen and pelvis to be sure that all the blood had been removed. There did not seem to be much soiling of the serous coat, either with the intestinal contents or with blood, except on the tissues immediately surrounding the bullet holes. When the final toilet of the peritoneum had been made, the exploratory incision made in the abdominal wall, which had, *pro re nata*, been lengthened to seven inches, was closed with silkworm gut sutures and a small drain of iodoform gauze left in the end of the wound first made. This wick of gauze remained in place until the bowels had been moved twice, but there was no dressing and no manipulation of the wound with irrigation that disturbed the wound, until that wick of gauze was taken out. The patient's bowels were tied up with opium for two days and he was given hypodermics of morphine for pain, but the bowels moved on the third day and there was no vomiting after the second day. All stitches in the abdominal wall were out at the end of a week.

Of course the fine Lembert sutures are usually left *in situ* and are eventually absorbed. They usually cause no difficulty, unless they have been accidentally carried too deep and involve the lumen of the gut, and in that case sometimes cause local infection, which if insignificant is cared for by the system, but if considerable the infection may become general and a general peritonitis follow. In the case reported no untoward symptoms arose and the young man went home at the end of three weeks. Today I called up his father, who reported that his son had had no sickness or accident since that time, weighed about 160 pounds, and was the picture of health and strength.

The second case was that of a woman about fifty years of age, who had suffered for a number of years from a long and increasingly complicated rectal disorder. She had passed through many cycles of advice and discouragement and at the end of it all was no better. She came to me about three years ago, giving the history of increasingly difficult defecation with stools gradually increasing in size. Local examination showed no induration of the abdomen at any point, comparatively little tenderness, no loss of flesh, and no cachectic pallor. The patient was fairly well nourished, ate and slept well, but was somewhat neurotic and had a sense of fullness in the abdomen at all times. Rectal examination did not show any bulging of the rectum or anus, no enlargement of glands, no history of venereal disease. She was married but had no children; husband healthy and robust, with no history of venereal disease. Five members of her own immediate family had died of tuberculosis and one sister at that time was in Colorado under observa-

tion for suspected tuberculosis. Dr. Leonard Retz, under my direction, made a series of x ray plates, with different times of advancement of the intestinal contents. These showed nothing that could be interpreted as growths, but simply emptying viscera. The stomach and small intestines were normal in function, no gallstones, but the descending colon showed a tortuous, very much diminished lumen for about four inches, with an entirely patent bulging gut at the lower end of this tortuous canal. The stools, that had with great difficulty been expelled before the operation, were soft, varying from the diameter of an ordinary lead pencil to that of the lead of the pencil.

The clinical history was such as to lead to the inevitable conclusion that there was a malignant growth, but the personal history of the patient was at entire variance with that conclusion. What occlusion there was of the colon was in the descending arm and did not involve the last four inches. Reasoning by afterresults, this condition must have been caused by some low grade tuberculous ulceration, long since quiescent but continually more potent, until something had to be done.

The full details were explained to the patient and her husband, with all the dangers and the possibilities. With the assistance of Dr. Rasbach, Dr. Leonard and a competent nurse I undertook the operation in a private house. I took with me several books of Lembert sutures, some Murphy buttons, surgical dressings, and other operating paraphernalia from my own office. After careful pre-operative and surgical preparation, which included no food for twenty-four hours, a median incision was made and extended until a complete inspection of the colon was possible. A part of the transverse colon was then selected and drawn into the wound, packed about with sterile compresses, and the colon opened on the side opposite the mesenteric attachment and the male portion of the Murphy button was inserted and held in place by means of a hemostatic. A pursestring suture of fine white silk, but not so fine as the Lembert suture silk, was passed around the protruding end of the button, in the serous and muscular coats, but not impinging on the mucous coat. This was held taut. Then a similar opening was made in the part of the descending colon below the cicatrix, in the bulbous portion, the female end of the button inserted, a pursestring suture passed about this opening, and the end of the button was held by Dr. Rasbach by grasping that portion of the button through the gut wall. Then the pursestring suture was drawn tightly around this latter portion, narrowing the opening until the serous coverings of the gut from both sides of the Murphy button were brought into apposition when the button was snapped together. When the two ends of the button were snapped together and before the serous surfaces were too tightly clamped, a careful examination was made to be sure that there was no leakage, then the two parts of the Murphy button were clamped tightly, but not enough to cause strangulation. A single row of Lembert sutures were inserted in the serous surface about one quarter of an inch apart connecting the serous surfaces on the one side of the button

with a serous surface on the other side. These were accurately tied, and the serous coats were cleansed from any possible contamination by the bowel content, and the whole mass was returned to the abdominal cavity. I hope that I have made this clear.

At the time of the operation there was almost entire occlusion of the descending colon, probably from cicatricial contraction of the lumen of the gut from, to me, causes unknown, but supposed by me to have been tuberculous. There was no specific history and none could be elicited and none suspected. The occlusion was relieved by short circuiting the colon from a place well above the stricture to a place about two inches below and this was done by inserting a Murphy button. I realized the difficulties of this short circuiting and told the family that that piece of gut might later fill up and cause pain, perhaps also some necrosis, in case it did not empty. A realization of this possibility did not deter me from leaving it, but a more complete operation would have been to short circuit the gut and then to excise the stricture and the portion above it that was left out of the current, but I thought best not to prolong the operation and hazard the patient's recovery by prolonging the shock. She was given an anodyne and put to bed with the foot of the bed elevated, and food and water were withheld for twelve hours. The dressing was a simple dry dressing on the surface, with silkworm gut sutures and a simple iodoform gauze drain extending down to the button, which was left *in situ* superficially and that gauze drain was not removed until her bowels had moved. The first movement showed the characteristic movements with colon operations, with some blood which did not reappear after the button sloughed away at the end of seven days. She was kept on a liquid diet for two weeks and soft food for a month, but was given no anodyne after the first three days. There was no elevation of temperature when the button came away.

The patient is alive at the present writing and as well and healthy as women of her age are expected to be. There has been no cachexia, no enlarged glands, no stoppage of the bowel, no induration, and there has been no aftertreatment with tuberculosis antitoxin or has there been any specific treatment with mercury or salvarsan. I go into these details as the explanation of the stricture was, and still is, unsatisfactory, but the relief has lasted for three years and I am sure if there was any taint of malignancy there would have been evidences of return long before this. She was a music teacher and the wife of the mayor in a city of a neighboring state. Her weight before the operation was 132 pounds and a few days ago when weighed in my office her weight was 148 pounds. She suffers from periodical attacks of high blood pressure, but has practically no abdominal symptoms. She has one or more bowel movements every day, normal in size and consistency, with a simple hepatic stimulant. She is never depressed nor melancholic. I do not presume to state what was the real cause of the stricture, but feel that malignancy can be ruled out. The unused circuit in the colon still remains, but with little or no untoward result.

Spontaneous Pneumoperitoneum Demonstrated by the X Ray in Acute Gastrointestinal Perforations*

By WILLIAM A. KELLOGG, M. D.,
New York,

Adjunct Attending Surgeon, Bellevue Hospital.

In most acute perforations of the gastrointestinal tract the clinical picture is pathognomonic, but occasionally the symptoms and physical signs are so atypical that a diagnosis is difficult. In such a situation the possibility of demonstrating with the fluoroscope the presence of free air in the peritoneal cavity should be considered, as is illustrated by the following case report:

CASE.—The patient was a male, aged fifty, of Turkish nationality. He spoke very little English and the only information obtainable on admission was the occurrence of severe pain some twelve hours before, with one attack of vomiting, and a marked subsidence of symptoms since. The house surgeon found generalized abdominal rigidity and tenderness and at first considered it an acute abdomen, but after the patient was made comfortable in bed, the rigidity diminished and he improved so rapidly that no attending surgeon was called.

The patient was seen on the attending surgeon's rounds in the afternoon, sixteen hours after the onset of the attack. He was smiling, sat up in bed easily, and there was no complaint of pain. He did not appear acutely ill. His temperature was 100.4°, respiration 24, pulse 96, and excellent in quality. The blood count was 12,000 total, polymorphonuclears 88 per cent. The urine showed a few granular casts and an occasional white blood corpuscle.

Physical examination at this time showed the patient's abdomen to be flat and soft, with only a slight suggestion of muscular spasm in the epigastrium, which was thought to be more or less voluntary, as it was difficult for the patient to understand what we wished him to do. There was only slight tenderness in the upper abdomen, even on considerable pressure. No obliteration of liver dullness on percussion could be demonstrated.

In view of the history and rigidity observed by the house surgeon on admission, a perforation of the stomach or the duodenum was naturally considered, but the clinical picture was so unlike that of a ruptured ulcer of sixteen hours' duration that we hardly felt this could be the actual pathological condition. We had almost decided to wait for further developments when Dr. Edwin Beer fortunately suggested a fluoroscopic examination and the diagnosis in a very puzzling case was made absurdly easy by observing the air line between the liver and the diaphragm.

On operating, an upper right rectus incision was made, but before opening the peritoneum saline was poured into the wound so that the air in the abdominal cavity was seen to bubble through the water when the peritoneum was incised. There was a small amount of stomach contents between the liver

and the duodenum, and a moderate degree of localized peritoneal irritation. The perforation was a small one near the pylorus on the anterior surface of the stomach and was plugged by a bit of omental fat so that nothing escaped until this was wiped loose. This sealing off of the perforation accounted, of course, for the absence of progressive symptoms. The perforation was closed with three purse-string sutures, reinforced by a piece of omental fat. A posterior gastroenterostomy was performed, the peritoneal toilet completed, and the wound closed in the usual manner with a cigarette drain through the peritoneum. The patient made an uneventful recovery except for a slight infection in the upper angle of the wound and when last heard from, five months after the operation, was in good condition. A search of the literature dealing with this subject reveals only a few reports in which this aid to diagnosis has been utilized.

In 1916 Robert Lenk (1), a military surgeon working on the Isonzo section of the Eastern front, reported the x ray findings in fresh gunshot injuries of the abdomen. He particularly emphasized those cases in which the x ray showed the presence of air between the liver and diaphragm, establishing the presence of a gastrointestinal perforation. He suggested that this method would be of value in civil practice in the diagnosis of perforated ulcer.

Dr. Walton Martin (2) in 1917 reported a case presenting conflicting abdominal and pulmonary signs in which an x ray photograph had been taken with the idea of demonstrating pneumonia. Dr. LeWald, the röntgenologist, observed an area of lessened density between the liver and diaphragm and suggested that there was free air in the peritoneal cavity. On the strength of this Dr. Martin urged an operation, but it was refused by the medical attendant. Subsequently the patient manifested a fluctuating mass in the right flank from which pus was evacuated. Dr. Martin regarded the primary condition as probably a subacute duodenal perforation.

The difficulty of diagnosing perforations in typhoid fever is frequently experienced, so the following case report published in 1919 by Dr. Walter E. Danby (3) is of unusual interest.

The patient had been under observation at Johns Hopkins Hospital for two weeks and the case was regarded as probably typhoid, although the laboratory findings were negative. Upon the development of obscure abdominal symptoms a possible perforation was considered. Some of the consultants suggested the diagnosis of acute miliary tuberculosis with peritoneal involvement. For this reason an x ray of the chest was taken. This fortunately showed the upper abdomen and demonstrated free air between the liver and the diaphragm. The op-

*Reported from the Fourth Surgical Division of Bellevue Hospital; case report presented before the Surgical Section of the New York Academy of Medicine, May 6, 1921.

eration disclosed a large typhoid ulcer perforation, which was sealed over by omental adhesions.

In attempting to use this means of diagnosis, it should be remembered that the air will rise to that part of the abdomen which is uppermost, whether the hypochondrium, the flank, or the pelvis. It is also possible that the air might be held by adhesions in the region of the perforation. Before x raying the patient, therefore, he should be placed in such a position that the air will rise to the part of the abdominal cavity which is easiest to expose, and the plates should cover every area suspected of being

the site of the perforation in case the air should be encapsulated by surrounding adhesions.

The Diagnosis and Treatment of Gallbladder Disease*

By ABRAHAM O. WILENSKY, M. D., F. A. C. S.,
New York.

Disease of the gallbladder and biliary apparatus—cholecystitis, choledochitis, cholangitis and cholelithiasis—is most commonly an affection of middle age, occurring with special frequency in women and closely associated with the incidence of pregnancy. There is, however, no restriction of this disease to the middle periods of life and many cases probably originate at a very early age, under fifteen years, and persist with no or only indefinite symptoms until later.

Abundant surgical experience teaches that the various pathological pictures which one can encounter in the manifestations of this disease are essentially the following:

1. Gallbladders of a practically normal histological structure. There may be many or few stones, or a single fairly large stone is present, which, becoming encysted in the neck of the gallbladder or cystic duct, gives rise to hydrops.

2. Large distended gallbladders, showing histologically more or less atrophy and containing many or few stones. Stones may be present in any of the ducts.

3. Gallbladders in which infection has taken place. These include empyemata of the gallbladder (or infected hydrops), acute and chronic cholecystitis with or without productive changes in the gallbladder wall, all of these with or without stones. Pericholecystitic abscesses with and without perforation of the gallbladder wall may complicate the picture. Stones may be present in any of the extrahepatic or intrahepatic ducts and may or may not be associated with a cholangitis.

4. The end results of group 3. The gallbladder may be larger or smaller than normal, may be much thickened or much thinned, and is usually much deformed. In some of the cases the gallbladder is so shrunken, that, when no stones are present, a natural cure may be approximated. The amount of pericholecystitis may be so extreme as to be capable of producing symptoms of its own accord.

5. Any of these types associated with a swelling of the head or head and body of the pancreas. The

clinical picture may not be distinctive, or it is marked by the characteristics of a fulminating acute hemorrhagic pancreatitis.

In any of these cases the sequence of events in the development of the finished pathological and clinical picture varies with the nature of the inciting agent. In some of the cases the disease is initiated by a frank infection; in these the infection may begin as a catarrhal cholecystitis, or the first manifestation may be that of an acute empyema of the gallbladder. In others the etiological cause seems to be a disturbance of the cholesterolin metabolism. Most of these have their beginning in pregnancy or in the postpartum period, and the symptoms are directly due to the stones acting as foreign bodies. In much the larger number of cases the mechanism includes both infection and disturbances of metabolism acting alternately or together and with various degrees of severity. Depending upon the factor which is uppermost at the time the patient is seen, the stage of the process, and the presence or absence of complicating factors which now become numerous, the pathological picture shows wide variations. The important point to remember is that all of the pictures described in this communication are but stages of one another and the ultimate development is only a question of time.

The advance of the pathological process is, however, unfortunately associated with complicating changes in neighboring viscera. Graham has shown that all cases of cholecystitis are accompanied by inflammatory changes in the liver parenchyma itself. These vary from an infiltration with small round cells to necrosis with fatty infiltration, and in chronic cases there are changes suggestive of cirrhosis of the liver in its early stages. There has been some experimental work done (Ogata, Rous and Larrimore) to show that in human pathology these liver changes probably result from a combination of infection and biliary stasis. In intrahepatic cholelithiasis a form of biliary cirrhosis is fairly common.

There is considerable clinical evidence to show that advanced disease of the biliary system is associated with changes in the pancreas; these latter are of an infectious origin and are due to the spread

*From Mount Sinai Hospital. Read at a meeting of the Harlem Medical Society, February, 1921.

of bacterial toxins along the lymphatics into the substance of the pancreatic gland. Clinically the anatomical changes may not be productive of immediate symptoms—except, perhaps, those of an acute hemorrhagic pancreatitis—but ultimately these give evidence of their presence in one way or another.

One should not forget that acute infections of the gallbladder can produce perforation and either a general peritonitis, which is rather rare, or a localized pericholecystitic abscess, which is rather common; and that chronic infective processes associated with stones can produce chronic penetrations and perforations into adjoining viscera and produce such a stubborn pathological process as to result finally in a fatality. Under the latter conditions a cholangitis develops and plays a prominent part.

Of all the varied pathological conditions to which disease of the biliary tract may lead, and of all of the complications which may occur, the most to be feared is a true infection of the intrahepatic bile passages. True infectious cholangitis is a most serious lesion, not rarely resulting in a fatal issue, marked with chills and fever and other signs of a high grade of intoxication and frequently running a rapid course; in its milder forms it leads to connective tissue changes in the liver parenchyma and commonly a precipitation of stones in the intrahepatic biliary passages is part of the pathological picture.

In order to obviate these unnecessary complications and sequelae of gallbladder disease it is essential that the condition be correctly diagnosed at a comparatively early stage of its development. Unfortunately, however, there is not available at the present writing any method of precision for this purpose except in a very small minority of the cases. One must, therefore, in the greatest number of the cases, rely on the general manifestations of the disease and on those elicitable indirect data which, by their presence, give presumptive evidence of the presence of diseased processes in some part of the biliary system.

Of all of these the history is most important. These include 1, cases with definite attacks of gallbladder colic; 2, the cases with indefinite symptoms referred to the right hypochondrium, or to the stomach; and 3, the cases with the clinical picture of an acute intraabdominal infection localized in the right upper quadrant of the abdomen. These various clinical pictures differ essentially in the presence or absence of definite attacks of biliary colic. When these attacks are present, either observed by the physician or so well described by the patient as to correspond to our notions of what these should be, they furnish indubitable and the most important single evidence of the presence of some form of disease in the gallbladder or bile ducts.

The physical examination yields the second best data useful in the making of the diagnosis. The possible data may be, 1, entirely negative; 2, partially positive; or 3, entirely positive. The definitive data include the presence of a palpable mass, the local and general signs of peritoneal inflammation or irritation, and the presence of jaundice. When the evidence is entirely positive it is always of so decisive a nature as to make an immediate diagnosis

possible; this is most likely to happen in the acute inflammatory cases. In the chronic cases the physical examination usually yields negative data.

In the absence of definite criteria, either in the history or in the physical examination, the diagnosis of gallbladder disease is always a presumptive one except in those fortunate instances in which the x ray is capable of yielding positive evidence of the presence of calculi. These positive evidences are, however, neither the rule nor very common, so that in many of the cases of gallbladder disease operation frequently assumes the characteristics of an abdominal exploration.

It is rather premature, at the present writing, to formulate the final opinion of the value of the intraduodenal use of magnesium sulphate (Lyon's test) in the diagnosis of gallbladder conditions. The method needs much more extensive experiment and use and the procedure ought to be further simplified in order to make it the basis for reliable work by the general practitioner. The method, however, holds forth promise.

Medical treatment of gallbladder disease can at most be only palliative. To those of us who see these conditions demonstrated day after day on the operating table, from the very simplest of diseased processes to the most complex, and who realize the seriousness of the late complications, it is inconceivable that medical therapy can ever accomplish a permanent cure. And if one realizes these facts it is apparent that the only efficacious treatment is that yielded by surgery. Those of us who see the late results of neglected gallbladder disease are impressed with the great necessity of operating upon these patients at the earliest opportunity in order to minimize the risk of operating, which is much greater in the late cases, and in order to obviate all the secondary changes in the liver and pancreas.

One should not be led astray by the enthusiasm of Lyon as regards the therapeutic possibilities of his method. With the presence of stones, or the results of infection, the method at most can be only palliative, or perhaps adjuvant to the very necessary surgery. Any condition of a nature more complicated than the simplest is practically entirely beyond the reach of the method for the procurement of permanent results.

The mortality in gallbladder operations is dependent upon the presence and number of complications, and upon the presence of associated conditions. The presence of an associated cholangitis is a most serious matter. With common duct obstructions the mortality may run as high as fifty per cent. In uncomplicated cases, the presence of disease in the lungs, heart, or kidney plays a most important rôle in the mortality statistics. All of these facts have extremely important bearings, inasmuch as at an early stage of the primary disease in the gallbladder these either do not exist or have not been aggravated to such an extent as to increase the risks of operative intervention. With the removal of these handicaps—which can only be accomplished by early surgical intervention—the mortality of operation upon the gallbladder should not be more than two or three per cent.

The Nonsurgical Drainage of the Gallbladder as an Aid in the X Ray Diagnosis of Gallstone Disease

By SAMUEL WEISS, M. D., F. A. C. P.,
New York,

The röntgen diagnosis of gallstones within the past few years has almost been accomplished by the use of new and powerful apparatus and improved technic. Carl Beck, in 1899, demonstrated a röntgenogram of biliary and hepatic calculi. Since then frequent attempts have been made by men to show gallstones with more or less success. Pfahler, Case, Cole, and George are among those who have been enthusiastic in their endeavor to demonstrate the feasibility of the röntgen ray method of detecting calculi. Pfahler believes that about fifty per cent. of stones are demonstrable. Case is of the opinion that when gallstones are present he can demonstrate forty or fifty per cent. Cole regards catharsis and fasting as an essential preliminary to plating. George and Leonard lay claim to eighty-five to ninety per cent. success.

The composition, size, number, and situation of the gallstones, their enveloping medium, the amount of obstruction by liver tissue, the intervening adipose tissue, the preparation of the patient, and the technic, all are factors affecting the demonstrability of stones. Pure cholesterin stones have slight density and are more difficult to show. The mixed type of stones, containing cholesterin, bilirubin, and calcium salts, are most common and their density is proportionate to the amount of lime present. Stones composed wholly of lime salts cast the deepest shadows. Large stones, even though poor in calcium, and numerous small stones massed together are demonstrable. Bile is a poor conductor of the rays, and the presence of stones in a bile filled and distended gallbladder do not give satisfactory shadows. The density of the liver tissue, by obscuring the shadows of the stones, is a serious obstacle to their detection. A corpulent individual is not a satisfactory patient for röntgenography of the gallbladder.

In 1917, the late Dr. Meltzer, writing in the *American Journal of the Medical Sciences*, demonstrated the action of a twenty-five per cent. magnesium sulphate solution when applied to the mucous membrane of the duodenum. This application caused a complete local relaxation of the intestinal wall. It did not exert such an effect when the salt was administered by the mouth, that is, when it had to pass through the stomach before it reached the intestine. He further stated that the application of a twenty-five per cent. solution of magnesium sulphate by means of the duodenal tube may relax the sphincter of the common duct and permit the ejection of bile, and perhaps, even permit the removal of a calculus of moderate size wedged in the duct in front of the papilla of Vater.

Immediately after the publication of Meltzer's paper, Lyon, of Philadelphia, demonstrated that the local use of magnesium sulphate in various strengths in the duodenum of human beings would promptly deliver bile through the duodenal tube in varying

quantities and of various quality. It would do this when the duodenum was previously bile free, indicating that the magnesium sulphate had relaxed the sphincter action of Oddi's muscle. Further than this it was noticeable that the character of the bile recovered by means of the duodenal tube underwent certain definite changes in color and viscosity, first a light lemon to golden yellow, then a deeper, richer, more syrupy golden yellow, and finally to a uniformly light lemon yellow, thinner and less syrupy than either of the first two; and that this sequence occurred in all normal cases.

Two years later Rehffuss, of Philadelphia, published a paper on the Medical Treatment of Biliary Affections, in which he described the method of obtaining bile and treating the biliary apparatus through the duodenal tube. Since the publication of Meltzer's, Lyon's and Rehffuss's papers I have made several hundred observations of the practicability of a nonsurgical method of biliary drainage. With certain exceptions, it is possible to drain the gallbladder wholly or partially of its fluid contents, to drain the bile ducts, and to obtain bile freshly secreted from the liver cells. Furthermore, it is possible to segregate the bile from these several sources by collecting it in individual bottles for chemical, microscopical, and bacteriological examinations that give us a direct method of differential diagnosis in diseases of the biliary system.

The röntgen examination consists of direct examination of the gallbladder region to determine whether visible shadows can be detected; whether the gallbladder itself contains inspissated bile, or its walls are thickened or calcified. Indirect signs obtained in the course of a routine examination of the digestive tract (Carman) are: 1. Gastric spasm; 2, six hour residue in the stomach or duodenum; 3, fixation of the pyloric end of the stomach, duodenum or hepatic flexure; 4, drawing of the stomach to the right by adhesions, or displacement to the left by an inflammatory mass about the gallbladder; 5, increased gastric peristalsis; 6, demonstration of Riedel's lobe of the liver; 7, localization of tender point over the gallbladder area; 8, demonstration of an organically normal stomach and duodenum, thus excluding them as probable causes of the symptoms. The most common lesions giving rise to symptoms which are often confusing are gastric ulcer, duodenal ulcer, cholecystitis and appendicitis. In the absence of peptic ulcer, the gallbladder and appendix must be considered.

In examining the plates taken of patients suspected of having gallstones, my attention was directed to the greater number of shadows visible in the gallbladder region of some patients than in others where the same röntgen technic was employed. After careful investigation I found that drainage of the gallbladder through the duodenal tube after the introduction of magnesium sulphate,

permitted better demonstration of the calculi with the rays. The accidental discovery caused me to "sit up and take notice," using the vernacular; that is, I experimented with the same individual before and after aspirating bile through the duodenal tube and the results were phenomenal. Where in one case there were none or barely perceptible shadows in the gallbladder region before duodenal drainage, they were visible after aspiration. I did not permit my enthusiasm to wane but kept up my investigations and, where possible, followed the patient to the operating table and found that the diagnosis was corroborated.

For the benefit of the uninitiated it will not be amiss to mention the method of obtaining the bile through the duodenal tube. To make possible an accurate diagnosis of the duodenal biliary zone it is necessary that we adopt means to prevent cytological and bacterial contaminations from the teeth, tonsils, respiratory tract, and stomach from confusing us in our interpretations of duodenal and biliary materials. To prevent this as far as possible I have adopted the method advocated by Rehlfuss and Lyon. The patient is instructed to purge himself the night before with castor oil and in case the results are not satisfactory to use an enema in the morning. He is also instructed to fast prior to the examination. When the patient is not to be x rayed on the same day I omit the castor oil and enema. The mouth is rinsed with some antiseptic solution, a sterile duodenal tube is passed into the stomach, and the contents of the fasting stomach aspirated. The stomach is then thoroughly rinsed and the patient is given a glass of sterile water to drink while slowly swallowing the tube to the duodenal point. In some cases I place the patient on

his right side, while in other cases this is unnecessary as the tube slips into the duodenum readily. The time required for the entrance of the tip into the duodenum varies in each individual, and also depends upon the tube used. The bile is readily recognized by its appearance, and it will be noticed that the flow is intermittent. Failing to obtain bile after a certain reasonable time, or if the flow is not sufficient, the duodenum is douched with about fifty to seventy-five c.c. of a twenty-five to thirty-three per cent. solution of magnesium sulphate. Where the gallbladder is found to be atonic it is necessary to restimulate its contraction by douching again with half the amount of magnesium sulphate.

Failure to obtain bile may point to the following conditions:

1. Obstruction of cystic duct by, a, stone or stones; b, adhesions or angulations; c, pressure from without, tumors, lymphatic glands; d, inspissated mucus—hydrops.
2. Gallbladder contents may be entirely calculi and no, or relatively little, bile.
3. Weakness of gallbladder musculature—atony, dilatation, or too weak to move its fluid contents.
4. Tarry bile.
5. Fibrosis of the gallbladder.

The scope of this paper does not embrace the technic for taking the plates nor do I wish to intimate that other methods may not be employed and the same results obtained. The purpose sought at this time, however, was merely to focus attention on the diagnostic and therapeutic possibilities involved in the method, with the hope that a more general interest and a wider application of the procedure might be stimulated among the profession.

616 MADISON AVENUE.

Carcinoma of the Stomach Simulating Pernicious Anemia*

By A. E. OLIENSIS, M. D.,

Philadelphia,

Associate in Medicine, Temple University, Visiting Physician, Samaritan Hospital.

The chief reason for presenting this case is not that it is unusual or new, for Osler and others have reported similar cases, but because of the interesting points presented by an analysis of the history, physical signs, and laboratory studies.

The patient, Mrs. H. C., widow, aged sixty-seven, white, was admitted to the Samaritan Hospital, February 23, 1921, under the service of Dr. W. E. Robertson. Her chief complaints were weakness, pain in the lower right chest and epigastrium, diarrhea (three or four bowel movements daily), numbness and tingling of hands and feet, and other paresthesia. The pain was of a shooting character, worse at night, and began in the lower right chest, radiating to the epigastrium. She said her health had been failing since May, 1920, at which time the pain first occurred. The pain usually occurred in

the early afternoon and lasted well into the night; as a rule she did not sleep well on that account. Her appetite was good; the pain was not influenced by the quality or quantity of food, nor was there any time relationship to food, but it was increased after a bowel movement. At times the patient suffered from nausea, belching, and a sour taste in her mouth, but she never vomited. There was some shortness of breath and she tired easily. She had a slight dry cough, and had lost thirty pounds in the past year. Menopause occurred at forty-two. She denied venereal infection. Had always had good health up to the present illness. She had two children, living and well; no miscarriages. Her husband was killed by accident twelve years ago. Her father died before she was born, cause unknown; her mother died of tuberculosis, and two sisters died of pneumonia. Her family history was otherwise negative.

*Read before the Northern Medical Society, Philadelphia, May 27, 1921.

Physical examination.—Temperature varied between 97° and 99.5°; pulse rate between 70 and 90; respiratory rate between 20 and 26. The patient was found to be very anemic. The mucous membranes were blanched and the skin of the covered parts resembled the whiteness present in an advanced case of parenchymatous nephritis, while the skin of the face and arms was of a lemon yellowish hue. There was no jaundice. Her adipose tissue was well preserved, but her musculature was flabby and her lips were cyanotic. Marked pyorrhea was present, with roots and snags. There was moderate general adenopathy. The chest was somewhat emphysematous. There was an area of fulness and dullness under the first portion of the sternum, continuous with the cardiac dullness and extending two and a half cm. to right of right sternal line and four cm. to the left of left sternal line. There was also an area of dullness posteriorly extending from a line across the spines of the scapulae down to ten cm. below, and laterally from left midscapular line to five cm. to the right of the spinal column. The right border of cardiac dullness was two and a half cm. to the right of the right sternal line, while the left border was in the midclavicular line. A slight thrill, systolic in time, was palpable at the base of the heart. A murmur was heard to the right of this area (systolic in time) and was conducted to the vessels of the neck. Heart sounds were weak. There was an accentuation of aortic second sound. The vessels were slightly fibrosed, pulses of low tension, and equal on both sides. Blood pressure, systolic 108, diastolic 84. The abdomen was found to be relaxed though frequently distended with gas; no fluid present, and no localized rigidity or tenderness. The liver was slightly enlarged, with upper border at fourth interspace and lower border five cm. below costal margin. The extremities showed no edema. Reflexes were exaggerated. There was a scar on the left leg which showed some ulceration, which the patient said was due to an old burn. Rectal and vaginal examinations were negative.

The features, then, which seemed most striking from the viewpoint of the history were: 1. Pain in the lower right chest and epigastrium, which had no relation to time or quality of food. 2. Gradual and progressive loss of strength and moderate loss of weight. 3. Paresthesia of hands and feet and of other parts of the body. 4. Fairly good appetite and tendency to diarrhea.

On physical examination the most striking features were: 1. The marked pallor, the lemon yellowish color of face and extremities, the weakness with preservation of adipose tissue. 2. Pyorrhea. 3. Physical signs of aneurysm of the arch of the aorta, confirmed by x ray and fluoroscopic examination, and by two Wassermann tests, both of which were reported delayed negative (which we considered positive because of the presence of the aneurysm).

The problem we were called upon to solve was the etiology of the anemia and the right inferior thoracic and epigastric pain. Was the cause intra-abdominal or extraabdominal? If intraabdominal, the most likely conditions seemed cholecystitis, gastric ulcer or cancer. If extraabdominal, aortic

aneurysm or pernicious anemia; or the combination of these two might explain the symptoms.

It was here that the laboratory was brought into play and added to the confusion. A fractional gastric analysis was made on February 24, 1921, which showed a free acidity varying from 54 to 70 and a total acidity varying from 92 to 126. Occult blood and lactic acid were negative. The gastric analysis was repeated several times with the same result, except that in a number of specimens the occult blood test was positive. A duodenal tube was introduced repeatedly but could not be made to enter the duodenum. X ray examination of the stomach showed absence of the duodenal cap. The gall-bladder was negative.

These data would favor the diagnosis of gastric ulcer but the history and physical findings were against it, and they did not seem sufficient to explain the anemia. The diagnosis of pernicious anemia was then considered; clinically it was a well marked case as shown by physical examination. We also felt that factors were present in this case which favored such a picture, namely, the severe pyorrhea and the possibility of syphilis. Intestinal parasites were ruled out by an examination of the stools.

Several blood counts were therefore made at different times with the following results: 1. Red blood cells varied from two to three million, usually two and one half million to the cm.m., while the hemoglobin varied from sixty per cent. to sixty-five per cent., thus giving a plus one color index. 2. The leucocyte count varied from 18,000 at the first count gradually coming down to 5,200, while the polymorphonuclears were usually above seventy per cent. 3. There were also slight poikilocytosis and anisocytosis, some granular degeneration, and occasional normoblasts. The blood picture, on the whole, looked more like a secondary anemia, due possibly to some focus of infection or suppurative process.

A number of urine examinations were also made, but had no bearing on the case except that they showed moderate interstitial involvement of the kidneys. Carcinoma was then considered but the high acidity, the relatively insignificant loss of weight, and the absence of other physical signs were against it.

What then was to be the treatment in such a case? An exploratory laparotomy would have cleared up the diagnosis, as far as the abdominal condition was concerned, but the patient's general weakness did not justify such a procedure. We therefore had to content ourselves with treatment more or less symptomatic. The pyorrhea was treated locally and several roots were extracted.

Alkalies and belladonna were given to counteract the hyperacidity, and small doses of neosarsphenamine were injected intravenously and other anti-syphilitic treatment was also given. Blood transfusion was recommended, but was practised only once on account of the failure of the donor to appear. The patient, however, did not improve but became gradually weaker, and died April 19, 1921, two months after her admission.

Editorial Articles

CYSTS OF THE MESENTERY AND THE MESOCOLON.

The diagnosis of cysts of the mesentery is difficult because objective signs are wanting, and in cysts of the mesocolon it is probable that a diagnosis has never been made before the abdomen was opened. The only clinical indication of cysts of the mesentery and mesocolon is an increase in the size of the abdomen. Their onset is insidious, and except in those cases where the patient has consulted a physician because of abdominal enlargement, the subject is not seen until a sudden pain occurs, due to an intestinal occlusion from the pressure exercised by the tumor. The umbilical region is the most frequent site of the pain at the beginning, and from there it spreads over the abdomen.

One of the principal characters of these tumors is that they are mobile transversely and frequently also horizontally. This transverse mobility distinguishes them from pancreatic cysts. By palpation their surface is found to be smooth and fluctuation may be elicited at certain spots, while a tympanic area is often present in front of the tumor. When the cyst has attained considerable size, certain disturbances resulting from compression arise, particularly of the digestive tract.

The evolution of these cysts is prolonged in most cases and the symptomatology is vague, none of the signs mentioned above belonging exclusively to them. Pancreatic cysts progress more rapidly and affect the general health in a marked degree. It is evident that a differential diagnosis between cysts of the mesentery and mesocolon must be made between many intraabdominal growths, particularly ovarian cysts, renal tumors, hydronephrosis, and pancreatic cysts, as well as acute inflammatory abdominal processes, such as appendicitis.

In addition to cysts of the mesentery and mesocolon properly speaking, other cysts may develop in the folds of the peritoneum and have the same pathology as the former. These are cysts included in the mesoappendix and gastrohepatic omentum. As to frequency of occurrence, the statistics published by Herrera Vegas showed ten cysts of the mesocolon, two of the mesentery, and one each of the mesoappendix, gastrohepatic omentum and gastrocolic ligament.

According to their contents, cysts of the mesentery and mesocolon may be divided into hydatid and serous cysts. The former are rare, and when they do occur there is an echinococcosis elsewhere in the

abdominal viscera. The serous cysts are due to some morbid change in the lymphatic system. Their walls are composed of three strata: a fibrous external stratum, a middle one, very vascular, composed of connected tissue, lymphoid tissue and lymphatic follicles, while the internal layer is epithelial. The contents are fluid, but become creamy, and when they contain blood assume a brownish hue. The specific gravity of the fluid is about 1.004. Chemically, the liquid is alkaline, containing albumin but no fibrin, carbonates, sodium chloride and sulphates in crystals. Throughout the fluid, cells are seen which have undergone fatty degeneration and even some fat globules may be present.

The origin of these cysts is generally attributed to the lymphatic system and three hypotheses have been put forward to explain them, namely, degeneration of the lymph nodes, ectasis of the lymphatic or chyloferous canals, and rupture of lymphatic vessels with encystment of the escaped fluids. It should be remembered that Dickenson has reported the pathological examination of a very complex growth of the mesentery containing cartilaginous and bony foci developed in masses of connective tissue and fat and cysts lined with endothelium with cilia. This case is unique, but from that very fact interesting.

MALIGNANT TRANSFORMATION OF DUODENAL ULCER

Malignant transformation of duodenal ulcer has been regarded as rare, but an exception to this is made by Meulle in his thesis (Paris, 1913) in the case of callous ulcer which appeared to have a great tendency to malignant change, since he found that it took place in fifty per cent. of the cases of ulcer. An examination of 216 cases of duodenal ulcer at the Mayo Clinic, in which resection had been performed, showed that cancerous change was present in sixty-three per cent. of the cases. Out of a total of thirty cases Kuttner found thirteen undergoing malignant transformation and this was found to be the case by Kelling in eight out of eleven cases of callous duodenal ulcer. The latter seems to have the same tendency to malignancy as callous ulcer of the stomach.

Perhaps the callous ulcers of the duodenum in which malignant transformation has taken place, are in reality gastric ulcers, because statistics deal with specimens excised in which the pyloric region is deformed and where a distinction is difficult to

make between the stomach and the duodenum. The starting point of the carcinoma often is not noted precisely and undoubted instances of ulcer-cancer of the duodenum are not common. Mayo even believed that malignant transformation is as rare in the duodenum as it is common in the stomach, having met with only four cases, and of these two were doubtful.

Moynihan has encountered two cases of duodenal cancer and believes that in one case at least ulcer was the starting point, because the patient had a past history of duodenal ulcer. Perry and Shaw recorded five cases, but in only two was the relation between ulcer and cancer distinctly proved at autopsy. Other cases have been reported by competent observers.

The rarity of cancer of the duodenum developing from ulcer may be accounted for by the fact that there is a greater infrequency of callous ulcer of the duodenum than of the stomach. Nevertheless, duodenal cancer certainly exists and further research is necessary to ascertain if it is really as uncommon as is generally supposed. Hartmann, of Paris, recently published three authentic cases while Houdard records another in which microscopical examination left no doubt that the growth developed from an ulcer.

PROTECTION FROM X RAYS.

In consequence of the death of Dr. Ironside Bruce, radiologist to Charing Cross Hospital, London, from the effects of continued exposure to x rays of a highly penetrating nature, and in view of the fact that the existing means of protection for workers was insufficient in the altered circumstances, a committee was appointed to consider the dangers involved in modern x ray work and to endeavor to suggest adequate measures for safeguarding the health of those engaged in this kind of work. The report of this committee, which has just been issued, lays stress on the danger of overexposure to x rays and radium, but states definitely that these dangers can be avoided by the provision of efficient protection and suitable working conditions.

The effects to be guarded against, so far as at present known, are, first, visible injuries to the superficial tissues, the skin, etc., which may result in permanent damage. Second, derangements of internal organs and changes in the blood, which are especially important as their early manifestation is often unrecognized. The committee urges, as a general precaution, that not more than seven working hours a week should be undertaken and that operators should spend as much time as possible out of doors. An annual holiday of one month or

two separate vacations of two weeks each are also advised, and nurses employed as whole time workers in x ray and radium departments should not be called upon for any other hospital service. Various precautions are mentioned in detail, and the importance of thorough ventilation is emphasized. Indeed, ventilation is regarded as being of supreme importance. The x ray room should not be below ground level. Artificial ventilation is necessary in most instances, for, with very high potentials, so-called coronal discharges are difficult to avoid, and these produce ozone and nitrous fumes, both of which are prejudicial to the operator. Dark rooms are capable of being opened up to sunshine and fresh air when not being used. The walls and ceilings of these rooms are best painted some more cheerful hue than black. Precautions against injury in using radium are also noted in detail.

The impression to be gained from a careful reading of the report is that the dangers attending the employment of x rays have in no wise been exaggerated. It is understood that the committee intends to add to the value of its work by endeavoring to find out a method of arriving at an accurate dosage of x rays. This is an exceedingly difficult problem, as the rays themselves are capable of wide variation with respect to their wave lengths, and the susceptibility of the body tissues varies also. The solution of this problem is urgent, as accurate knowledge of dosage is essential to the complete safety of the workers. It is hoped therefore that success will attend the efforts of the investigators.

PHYSICIAN AUTHORS: DR. CHARLES BALGUY

Dr. Charles Balguy was an English country physician of the eighteenth century, unknown to fame then and unknown to fame now despite the fact that millions of people have enjoyed his literary work, for in 1741 he gave Boccaccio's *Decameron* the English dress that it has worn ever since. The *Decameron* sold in bookshops today is the Balguy translation with modernized spelling and only a few slight modifications, generally for the worse. The editions of today also include two stories, exceedingly licentious, which Balguy thought it best to omit. The great difference in style makes it easy to detect these two. Prior to Balguy's there had been only one translation of the *Decameron* into English. It appeared in 1620 and was published by Isaac Jaggard. But this was a gross and unliturgical product, and beside, it was translated very inaccurately, apparently from the French version of Antoine Le Macon. Balguy's translation, made

direct from the original Italian, is a masterpiece of noble English and so vastly superior to the Jaggard folio in all respects that it was adopted by publishers as the standard and has been reproduced in all subsequent editions. The Jaggard translation quickly went into oblivion, where it has remained ever since. Only a few collectors of rare books know it now. In his preface, speaking of the *Decameron*, Dr. Balguy says: "This hath been reprinted an infinite number of times and translated into divers languages. Two translations there are in French that have come to my knowledge, and the same number in our own language, if they may be styled so, for such liberties are taken everywhere in altering everything according to the people's own taste and fancy, that a great part of both bears very little resemblance to the original." Up to the time of the Jaggard translation, however, the *Decameron* had been known in England only in fragments and Balguy's translation was the first and only one published after that put forth by Jaggard. The other translation to which Balguy probably refers is William Paynter's *Palace of Pleasure* (1566), which, however, contained only about sixty *Decameron* tales and was a mixture of Queen Margaret, Bandello, Straparola, Livy, Herodotus, Aulus Gellius, Boccaccio and others. But Paynter did not pretend to translate. He stole the tales of others and wrote them in his own way as his own—thereby creating a treasure house which many others after him pillaged, including Shakespeare, who got his plot for *Romeo and Juliet* from the *Palace*. In those old days, as Charles Whibley points out, plagiarism does not seem to have been regarded as a heinous sin.

Never has an edition of the *Decameron* carried Dr. Balguy's name. Edition after edition has been published either without any acknowledgment or with only a bare reference to the edition of 1741, despite the fact that they are printed practically word for word from the 1741 edition. Dr. Balguy himself was somewhat to blame for his obscurity, for his translation crept into the world anonymously and it is doubtful if the later publishers were aware of his connection with it or had ever heard his name. The translation was first published by R. Dodsley, the famous eighteenth century London publisher, when Dr. Balguy was thirty-three years old and it was a closely and well printed octavo of 591 pages, dedicated "to Backe Thornhill," a relative and friend of Dr. Balguy.

S. P. Addy, writing in the *Journal of the Derbyshire Archaeological and Natural History Society*, (Vol. 6, 1884), says: "My own copy of Balguy's translation was described by Mr. Quaritch, of whom

I bought it, as being bound in 'bright old calf.' The stories themselves are bright as Italian skies. . . . It was Charles Balguy's task to present those old stories in a fair English dress, and he accomplished that task well. His English is always pure, and some parts of the prose translation read like poems. His metrical versions have no great merit. They are merely such as a scholarly writer would make in an age when everybody imitated Pope. His prose has the true Addisonian ring and the archaisms which have been altered in subsequent editions have no uncouthness to the literary eye. Whether Balguy ever lived in Italy I know not, but he had certainly a scholarly acquaintance with Italian literature. . . . In his boyhood members of his family had espoused the cause of James Stuart, the Pretender. Had he lived in our time, he might have forsaken the older scholarship and written a good novel or two. As it was, he practised physic and contented himself with translating the *Decameron*. In 1741 the modern novel had hardly been 'invented' . . ."

Dr. Balguy came of an old Derbyshire family (originally de Balgi) who had been seated in that part of England since the time of Edward I. They were possessed of large estates which included the famous old Derwent Hall, where Dr. Balguy was born in 1708, the youngest of a family of five daughters and two sons. He was educated at the Chesterfield Grammar School, under the Rev. William Burrow, M. A. For many years the masters of this school were men of the first literary eminence and the school was reckoned one of the best in the north of England. Ellis Farnworth, translator of Machiavel; Halifax, Bishop of Gloucester; Dr. John Jebb, an eminent Eighteenth century physician; Dr. Samuel Pegge, the antiquary; Secker, Archbishop of Canterbury; Dr. Erasmus Darwin, grandfather of Charles and author of *The Botanic Garden*, and other notables were educated at this school. At the age of eighteen Balguy entered St. John's College, Cambridge, (July 5, 1725) and took his degree of Bachelor of Medicine in 1731. He was made a Doctor of Medicine at Cambridge in 1750. He died March 2, 1767, at the age of fifty-nine years and was buried in the chancel of St. John Baptist's church at Peterborough, where he had practised medicine for many years. A marble tablet on one of the chancel piers describes him as "a man of strict integrity, various and great learning, and of distinguished eminence in his profession." Whether he ever married is uncertain. Dr. Peege, his companion at Chesterfield, says he did, but there is no mention of wife or children in his will or on the memorial tablet.

Other than his translation of the *Decameron*, Dr.

Balguy's literary output was slender. In 1734 he contributed to the *Philosophical Transactions of the Royal Society* an account of "the dead bodies of a man and woman preserved forty-nine years in the moors of Derbyshire" and in 1736 he contributed to the *Medical Essays*. In 1758 he wrote the *Epistola de Morbo Miliari*, evidently a short Latin treatise on some form of pulmonary disease. Any other writing or translating he may have done is unknown. And few know that he translated that precious volume of tales of the days when "all men were gallants and all women grandes dames and all birds nightingales." But in that he has merely suffered the melancholy fate of most translators, for the way of the translator is hard. Only a few brilliant exceptions, such as Burton's *Arabian Nights*, Fitzgerald's *Omar*, Chapman's *Homer*, the *Plutarch's Lives* of Sir Thomas North, the *Rabelais* of Urquhart and Motteux and a few others such as these, are remembered. The majority are forgotten. Balguy has perhaps been more completely forgotten than any of the rest.

DOCTORS' FEES

The pronouncement of the Johns Hopkins Hospital authorities, that the surgeon should not charge more than a thousand dollars for any operation and not more than thirty-five dollars a day for attendance on any patient, has directed the attention, not only of the medical profession but also of the lay press, to the question of physicians' fees. One of the great difficulties encountered in discussing the question of physicians' fees is that of determining how large a part of the physician's time is devoted to eleemosynary work. Any effort to place an arbitrary and universal limit upon the fees to be charged would work a hardship in many instances and would be as little welcomed by the patient as by the surgeon.

The general practice in the medical profession as in transportation has been to "charge what the traffic will bear." In transportation one of the fixed charges is the free transportation of employees and their families. Some one must pay for these free rides and consequently their cost is merged in the general overhead and eventually figures in the cost of transportation charged against paying patrons. In very much the same way the members of the medical profession do a great deal of charity work. They attend patients both in and out of hospital from whom they never expect to receive any remuneration whatever. This service is part of the overhead in the practice of medicine and must be paid for by those who have the means to pay for expert medical advice.

The mere formulation of a rule by any one hospital cannot be expected to govern the actions of the profession as a whole. The vast majority of surgeons would be delighted to accept a fee of a thousand dollars for an operation and the number who have ever received any such fee is relatively small. But for the expert surgeon, who by specialization in some particular field and by reason of extraordinary skill has built up a national reputation, limiting the maximum fee to a thousand dollars would be unfair. Men of great wealth who require the services of such experts will not hesitate to pay many times this sum named and would consider the service rendered as entirely adequate.

Among lawyers we frequently hear of fees vastly in excess of anything paid to medical men and no question of profiteering is raised. It seems to us unfortunate that so conservative an institution as the Johns Hopkins Hospital should have taken action which has been construed by the general public as setting a maximum fee, though the hospital authorities no doubt would disclaim any such idea and probably intended merely to suggest a maximum fee for the members of its own particular hospital staff and had no idea of attempting to dictate to the medical profession at large in this matter.

PROFESSIONAL SECRECY.

The breach of professional secrecy in the Stillman divorce case has directed public attention in the United States to the question of professional secrecy as it applies to the physician. In Great Britain the subject came to the fore about the same time as a result of a ruling made by Mr. Justice Horridge to the effect that information acquired at a venereal clinic was not "privileged" but that the physician must testify or be subject to proceedings for contempt of court. This ruling brought the matter before the British Medical Association at its recent annual meeting and the subject was discussed at great length and with much diversity of sentiment. A resolution was first introduced by the council to the effect that when called into court the physician should obey the direction of the presiding judge regardless of the wishes of the patients. Eventually, however, another set of resolutions was introduced which recommended "that the association use all its power to support a member who refuses to divulge, without the patient's consent, information obtained in the course of his professional duties, except where it is already provided by the act of parliament that he must do so." Such an act of parliament already exists regarding the notification of certain diseases. It is intimated that an effort will be made to bring about a test case in England with a view to determining not only the precise legal status of the physician in the matter of professional secrecy but also the attitude of the judiciary and the public as well. It is contemplated that eventually the question of professional secrecy for

medical men in Great Britain will be definitely defined by act of parliament.

In the United States the courts have taken a rather more liberal view of the subject than that taken by Mr. Justice Horridge and where the physician has declined to answer on the ground of professional secrecy his actions have usually been upheld by the courts.

Many problems are presented, of course, in this matter of professional secrecy, particularly where criminal law is involved. On the whole, the attitude of the medical profession and the courts of the United States differs somewhat from that in Great Britain, both physicians and courts in this country being more inclined to recognize the claim of the physician for exemption from testifying where the testimony would involve a betrayal of professional secrecy. The public outcry against the doctor in the Stillman case, who, by the way, was an osteopath, shows that the public generally supports the medical profession in its efforts to preserve professional secrets as inviolate, even in the courts of law.

THE ORIENTAL SORE.

The last inquiry as to the etiology and removal of the oriental sore contradicts somewhat the classical literature which says that the majority of cases seem to be confined to one place and to exist under the same conditions. Cases outside this zone are rare. Those observed recently in Crete convince us that they are not ectopic, but seem to have a real hotbed there, the principal places being La Canée, Rethymno, and in all the region which extends from Héracleion to the Plain of Messara. It is found in the east, but rarely at Sitia. At Canée it is frequently found in the crowded quarters of the old town. In Crete, man alone seems to be troubled, and epidemiological investigations prove it transmissible without the intervention of a biting insect. Contaminated flies cannot transmit it after five hours. The report is fully given in the February, 1921, number of the *Annales de l'Institut Pasteur*.

SOUTH AFRICA'S NEEDS.

It does seem somewhat unfair to medical eyes that large fortunes, amassed during life in South Africa, particularly in mining, should go largely to English charities, and Dr. R. P. Mackenzie, in his address as retiring president of the British Medical Association, Witwatersrand Branch, dwelt somewhat bitterly on the fact that in his neighborhood the Chronic Sick Home at Rietfontein is quite inadequate for the numbers waiting, also that the only tuberculosis sanatorium is that provided by the Chamber of Mines at Spring Kell, and it is only lately that they have agreed to accept municipally paid for cases. A large bequest was made recently to hospitals in London by a man who had made his money in South Africa, yet only £2,000 came here—£1,000 to the New Somerset Hospital at Cape Town, £1,000 to the Kimberley Hospital. Naturally a man's thoughts turn home, but common justice demands a share of that gained in another country.

News Items.

Typhus on an Ocean Liner.—A case of typhus was discovered among the second cabin passengers of the *Aquitania*, when the ship reached quarantine a few days ago. The patient was a Russian refugee.

Colorado Hospital for War Veterans.—Under an Executive order signed August 20th by President Harding, the Veterans' Bureau has taken over the naval tuberculosis hospital at Fort Lyons, Las Animas, Colorado. It will be used as a tuberculosis institution for war veterans. The capacity is 780 beds.

War Nurses Sought for Relief Work in Russia.—War nurses will be recruited in the United States for aid in administering American relief to Russia's needy children, according to plans completed by Secretary Hoover. Several hundred nurses will be selected largely from the ranks of those who saw service in France.

Typhoid Fever Epidemic in New Jersey.—The State Department of Health has sent all its available forces to Burlington County where there is a serious epidemic of typhoid fever. It is said that more than two hundred cases have been reported in twelve towns of this county. Dr. J. B. Fitzrandolph, assistant director of the State Board of Health, and Dr. David Bowen, state epidemiologist, are in charge of the situation.

School for Ship Doctors.—Dr. William H. Dieffenbach, on behalf of the Board of Directors of the Broad Street Hospital, New York, announces that ship doctors are to have a medical graduate school of their own. He points out that maritime doctors would be enabled through such a school to perfect themselves in the latest technic of the profession, with particular attention to the diagnosis and treatment of transmissible diseases, in order to nullify the spread of ailments likely to develop into a plague.

School of Public Health at Harvard.—Through a gift of \$1,785,000, made by the Rockefeller Foundation, Harvard University will establish a School of Public Health. The purpose of the school is to train public health administrators, making of such work a distinct career rather than leaving it to general practitioners. Special courses in preventive medicine, tropical medicine, and industrial hygiene are already taught, but the enlarged school will offer opportunities in public health administration, vital statistics, immunology, bacteriology, medical zoology, physiological hygiene, and communicable diseases.

United States Civil Service Examinations.—The United States Civil Service Commission announces an examination for associate in clinical psychiatry and psychotherapy to fill vacancies in St. Elizabeth's Hospital, Washington, D. C., at \$2,500 a year. Papers will be rated as received until November 1st. There will also be an examination for röntgenologist, associate röntgenologist, assistant röntgenologist, and junior röntgenologist for positions ranging from \$70 to \$250 a month. Applications will be rated as received until December 1st. Further information may be obtained from the Civil Service Commission, Washington, D. C.

France in Danger from Epidemics of Cholera and Typhus.—According to cable dispatches from Paris, dated August 20th, France's health experts are beginning to worry over the fact that not having established a system of sanitary inspection of immigrants for contagious or infectious diseases, there is nothing to prevent the spread of these diseases into French territory.

Meeting of Maine Medical Association.—On June 27th to 29th, the sixty-ninth annual meeting of this society took place in Bangor. Dr. Theodore E. Hardy, president, and Dr. George R. Campbell, vice-president, presided. The following officers were elected: President, Dr. Addison S. Thayer, Portland; president-elect, Dr. Langdon T. Snipe, Bath, and secretary-treasurer, Dr. Bertram L. Bryant, Bangor.

Medical Intern, Saint Elizabeth's Hospital.—The United States Civil Service Commission announces an examination for medical intern to fill vacancies in Saint Elizabeth's Hospital, Washington, D. C., at \$1,200 a year and maintenance. The examination is open to both men and women. The positions are tenable for one year. Applications will be rated as received until November 1, 1921. For further information address Civil Service Commission, Washington, D. C., applying for Form 1312.

Infantile Paralysis in New York.—Ten cases of infantile paralysis have been reported in Westchester County, thirty-three in Utica, and others in various parts of the state, making a total of about one hundred cases. In Greene County there have been five cases with two deaths. In New York city, during the first eighteen days of August, fifty-eight cases were reported, all of a mild type, with eight deaths. Active steps are being taken by the health authorities of both state and city health departments to control the outbreak and it is said that there is no immediate cause for alarm.

Personal.—Dr. and Mrs. Gregory Stragnell, of New York, announce the birth of a daughter, on Wednesday, August 17th.

Dr. George O'Hanlon, general medical superintendent of Bellevue Hospital, and Dr. John W. Perelli, member of the Board of Trustees, have been made Chevaliers of the Crown of Italy by T. F. Bernardi, the Italian Consul General. The decorations were authorized in recognition of the work of the two physicians in the reorganization of the Italian Hospital, East Eighty-third Street.

American Society for the Control of Cancer.—Dr. John C. A. Gerster has been appointed chairman to organize a Metropolitan district for the National Cancer Week campaign, for an attack on cancer in Greater New York, Long Island and Westchester counties. Dr. George E. Armstrong, of Montreal, has undertaken to organize the society's work throughout the Dominion of Canada. Dr. Joseph Bloodgood, regional director for the States of Maryland, Virginia and Delaware, has asked Dr. Robert C. Bryan, of Richmond, to organize the State of Virginia. Dr. V. J. LaRose, of Bismarck, has accepted the chairmanship of North Dakota, and Dr. Fred E. Clow, of Wolfeboro, has been appointed chairman for New Hampshire.

American Gastroenterological Association.—At the twenty-fourth annual meeting of the American Gastroenterological Association, held in Boston, June 6th and 7th, Dr. Allen Jones, of Buffalo, was elected president for the coming year. The vice-presidents are Dr. George B. Eusterman, of Rochester, Minn., and Dr. R. Walter Mills, of St. Louis; secretary, Dr. Arthur F. Chace, of New York; treasurer, Dr. Clement R. Jones, of Pittsburgh, and recorder, Dr. Ernest Gaither, of Baltimore.

Died.

BANTLEY.—In Danville, Ill., on Tuesday, August 9th, Dr. Barth Bantley, aged seventy-four years.

BOICE.—In Sistrerville, W. Va., on Wednesday, August 3rd, Dr. John M. Boice, aged sixty-five years.

BROUGH.—In Boston, Mass., on Sunday, July 31st, Dr. David D. Brough, aged fifty-one years.

COLL.—In New York, on Wednesday, August 10th, Dr. Arthur P. Coll, aged fifty-five years.

COY.—In Napoleon, Ohio, on Tuesday, August 9th, Dr. Henry C. Coy, aged sixty-six years.

CRYER.—In Lansdowne, Pa., on Friday, August 12th, Dr. Matthew H. Cryer, aged eighty-one years.

DYER.—In Whitman, Mass., on Friday, August 5th, Dr. E. Alden Dyer, aged sixty-four years.

EISENBERG.—In Norristown, Pa., on Saturday, August 13th, Dr. Phillip Y. Eisenberg, aged seventy-four years.

FELTY.—In Gettysburg, Pa., on Sunday, August 7th, Dr. John C. Felty, aged seventy-two years.

FRENCH.—In Rochester, N. Y., on Thursday, August 11th, Dr. Robert T. French, aged sixty years.

GREEN.—In Long Gree, Md., on Tuesday, August 2nd, Dr. John S. Green, Sr., aged sixty-four years.

GRESHAM.—In Birmingham, Ala., on Saturday, July 30th, Dr. A. Belton Gresham, aged forty-four years.

HAMBRIGHT.—In Philadelphia, Pa., on Wednesday, August 10th, Dr. Edwin A. Hambright, aged seventy-five years.

HILLER.—In Bellefonte, Pa., on Monday, August 8th, Dr. Hiram M. Hiller, of Chester, Pa., aged fifty-four years.

HIRST.—In Salisbury, N. Y., on Monday, August 8th, Dr. Patrick J. Hirst, aged thirty-six years.

INGOLDSBY.—In Dorchester, Mass., on Tuesday, August 9th, Dr. Joseph E. Ingoldsby, aged forty-eight years.

LEIDY.—In Reading, Pa., on Monday, August 15th, Dr. Thomas H. Leidy, aged seventy-six years.

MAHADY.—In Rome, N. Y., on Monday, August 8th, Dr. Charles Mahady, aged forty-nine years.

MCWHORTER.—In Akron, Ohio, on Monday, July 18th, Dr. John S. McWhorter, aged eighty-three years.

MEIGHEN.—In Littleton, W. Va., on Tuesday, July 9th, Dr. Thomas H. Meighen, of Wheeling, W. Va., aged fifty-six years.

MINDEL.—In Wildwood, N. J., on Sunday, August 14th, Dr. Henry W. Mindel, of Philadelphia, aged seventy years.

MOSEMAN.—In Point Pleasant, W. Va., on Monday, August 1st, Dr. Elmore Moseman, aged sixty-eight years.

OVIATT.—In Cleveland, Ohio, on Monday, August 1st, Dr. Wilson H. Oviatt, aged eighty-seven years.

QUESTA.—In Arcade, N. Y., on Tuesday, August 2nd, Dr. Guido J. Questa, aged twenty-five years.

REYNOLDS.—In New York, on Tuesday, August 16th, Dr. William Myron Reynolds, aged fifty-nine years.

SWIFT.—In West Chazy, N. Y., on Wednesday, August 10th, Dr. Frederic N. Swift, aged fifty-seven years.

TAFT.—In New York, on Monday, August 8th, Dr. Robert McLean Taft, aged forty-seven years.

WATSON.—In Sheridan, Ark., on Thursday, July 18th, Dr. H. P. Watson, aged one hundred years.

WHITE.—In Indianapolis, Ind., on Wednesday, August 10th, Dr. Charles A. White, aged seventy-six years.

WHITTINGTON.—In New York, on Tuesday, August 16th, Dr. Samuel Betts Whittington, aged fifty-two years.

WILSON.—In Pleasure Ridge, Ky., on Wednesday, July 27th, Dr. Jasper M. Wilson, aged eighty-nine years.

WINANS.—In Belleville, N. J., on Tuesday, August 9th, Dr. Joseph Clark Winans, aged forty-two years.

Book Reviews

A PIONEER IN PSYCHOANALYSIS.

Addresses on Psychoanalysis. By J. J. Putnam, M.D., Emeritus Professor of Neurology, Harvard University. With a Preface by SIGMUND FREUD, M.D., LL.D. International Psychoanalytical Library, No. 1. London, Vienna, and New York: The International Psychoanalytical Press, 1921. Pp. 470.

In many ways these collected papers by Dr. J. J. Putnam are of historical interest. They should have a special value at the present moment, being presented at a time when the British Medical Association has given official approval of the methods of psychoanalysis. For many the name of Putnam gave a certain cloak of respectability to the movement of psychoanalysis in America. Now the official sanction of the British Medical Association will do much the same thing. Putnam was first opposed to the tenets of psychoanalysis and looked with scepticism, if not ridicule, on the theory which ascribed the neurosis to a sexual etiology. When Freud, Jung, and Ferenczi visited this country some years ago Putnam made their acquaintance and was impressed by their personalities and their earnestness. This visit marked the beginning of his interest in analysis. From that time on until his death some ten years later he was an earnest worker and a staunch supporter of psychoanalysis. He found that analysis offered a pragmatic method for the cure of the neuroses. He also fought valiantly to place the theories before his medical colleagues. In this battle he admitted his own initial resistances and did everything in his power through lectures and papers to show medical men that they were ignoring and combatting a theory which would prove the most useful that could be adopted in the treatment and understanding of the psychoneuroses. He was ever on guard against the weaknesses of analysis and tried to confirm each step he took. He followed closely Darwin's dictum of examining the point of view of his opponents with the same care as that given to the view he accepted and set forth.

No doubt it was difficult for him to overcome his original puritanical environment but fortunately he was honest and always open to conviction. This honesty is shown in the way he has admitted the narrowness of the views he once held. Another example of such fearlessness has been shown by the English neurologist Stoddart.

In reading the collected papers in this volume, which is the first issued by the International Psychoanalytical Library, one is struck by the effort Putnam made to show the harmlessness of the Freudian sexual theory. He felt that once this phase of the

theory could be robbed of its obnoxiousness it would be more readily accepted by the medical profession. Would that this were true. Unfortunately he did not realize that many personal weaknesses prevented an acceptance of a theory which, if followed, would ferret them out. He did not fully take into consideration the additional resistance which was caused by an unwillingness on the part of physicians to give up the old classifications—the last thread that bound them to their old professors.

In these papers we can follow Putnam when he tried to find out what the rebels in psychoanalysis had to offer. He sympathized with Jung's cravings for a metaphysical something which he could not find in following Freud too closely, but could not accept the conclusions as set forth by Jung, for they were too far from reality. It was this very reality which kept Putnam with his feet to the ground and his head up, for while he felt that he should like to see a fine philosophy evolved from analysis, still he felt the time inopportune as there was still too much work of a practical nature to be done. He clung with fervor to the belief that one day in the not too distant future analysis would form the foundation of a sublime philosophy. Perhaps his feelings were not far wrong. He saw how analysis had invaded almost every field of endeavor and he felt that it only required a correlation of this work to establish a new set of values. A following out of the "evaluation" of Nietzsche, but on a constructive plan.

The attitude of Adler gave him more pain, for he felt that Adler had much to offer, and indeed he admits that he derived

stimulation and received many fundamental ideas from Freud's former student. However, as in the case of Jung, he did not feel that Adler was right in the theories where he flatly contradicted Freud. So to the end of his days, while keeping his mind open to any criticism, he remained a true Freudian. He felt that the theories advanced by the Viennese savant were basic, and he found none by which they could be replaced. His rôle was not that of an original worker, as he added little new to the science of analysis, but he was a severe critic and used analysis in a practical way. His principal desires were to benefit his patients; to spread the gospel of psychoanalysis among his fellow workers; to see a new philosophy evolved from analysis. His first two wishes were fulfilled; the last remains to be accomplished by his successors.

In his addresses he cites many cases in detail which are of practical value, and he states lucidly

JAMES J. PUTNAM, M. D.

the views of the opponents of analysis as well as what he considers its weakness. His writing is always fluent and enjoyable and this set of addresses should prove of interest to all medical men whether they agree with analysis or whether they are in a position similar to that occupied by Putnam when he first heard of this strange gospel.

Freud has written a brief preface in his usual clarifying manner and Jones has presented an obituary in which he pays homage to this great veteran in psychoanalysis.

INSTRUCTION FOR DIABETIC PATIENTS.

A Primer for Diabetic Patients. A Brief Outline of the Principles of Diabetic Treatment, Sample Menus, Recipes, and Food Tables. By RUSSELL M. WILDER, Ph. D., M. D.; MARY A. FOLEY, Dietitian, and DAISY ELLITHORPE, Dietitian, The Mayo Clinic. Philadelphia and London: W. B. Saunders Company, 1921. Pp. 76.

The title of this work adequately conveys the scope of this rather practical little book, which aims to instruct the diabetic patient in some of the basic ideas employed in the treatment of diabetes. Briefly and clearly the authors describe the function of foods in the general normal metabolism, their caloric values, and their methods of estimation. Then follows a brief chapter discussing the various components of foods—carbohydrates, fats, and proteins—examples of which are given; the rôle that they play in the production of energy, individually and collectively; their transformation in the process of metabolism into simpler substances which may at one stage or another, depending upon the severity of the diabetes, prove detrimental to the patient. Emphasis is placed on the importance of the knowledge of the relative proportion of carbohydrates, fats and proteins in foods, for the wise selection of a diabetic diet and menu. To aid the patient in this, a short table of foods in common use is appended, giving the percentage values of fats, proteins and carbohydrates, in definite weighed amounts of the particular food in question. In all this the metric system is employed.

The review of the steps in the dietary management, in which the principles of graduated restriction of carbohydrates, fats and proteins as exemplified by the starvation diet, with a view to controlling the sugar excretion, so successfully advocated by Dr. Frederic M. Allen, will help the diabetic patient to understand his disease more thoroughly. It will enable the patient to realize what to him, straining under the deprivation of foods to which he has been accustomed, may seem cruel and useless, is logical and necessary.

The complications as to the teeth, and skin, seen in the course of the disease, the importance and prevention of acidosis and coma, are duly stressed, and treatment briefly but clearly indicated. The value of the examination of urine by the patient himself, the methods and their significances also are referred to.

The latter part of the book deals largely with the question of diet, menus, and recipes. These the patient as well as the nurse will find exceedingly helpful, inasmuch as their selection is presented not in any haphazard fashion, but with a careful regard of the needs of the mild, moderate and severe diabetic. This book should be of value to the patient, as well

as the nurse, not to speak of the general practitioner who would acquire an intelligent cooperation on the part of his patients.

HEMORRHAGE.

Le Emorragie. Nelle Ferite d'Arma da Fuoco in Guerra. Dott. GIUSEPPE FANTOZZI, Assistente e Libero Docente, Institute di Clinica Chirurgica della R. Università di Pisa; diretto dal Prof. D. Taddei. Pescia: Benedetti & Niccolai, 1920. Pp. vii-385.

This is in many ways a remarkable work, consisting as it does of 376 pages of text and 116 pages of bibliography, all on the subject of hemorrhage. The writer begins with a section on the history of surgery in relation to hemorrhage, especially that of war injuries; he then goes on to the anatomy of the bloodvessels and to the blood, with special reference to coagulation. The main body of the text is then set forth, in which there are noted the following divisions: Wounds of bloodvessels; hemorrhage in general; primary external hemorrhage; interstitial hemorrhage; hemorrhage of the body cavities; secondary hemorrhage. Then follows an appendix which takes up shock, blood transfusion, and trench methods of arresting hemorrhage. Even the bibliography is systematically divided into sections on general consideration; bloodvessels; the cranium; the thorax; the abdomen; shock; and blood transfusion.

A prodigious amount of work must have been entailed in the preparation of this treatise and the author's personal views are so intermingled with citations from the literature that nothing of importance in any language can have escaped his searching eye. There is a characteristic European painstaking thoroughness about the volume and it would seem to deserve a place among the classics on the subject.

SURGICAL CLINICS.

The Surgical Clinics of North America. New York Number, April, 1921, vol. i, No. 2. Philadelphia and London: W. B. Saunders Company, 1921.

This number presents twelve clinics given by surgeons in various New York hospitals. Perhaps the most interesting article in the series is the clinic by Dr. Willy Meyer on The Importance of Posture in Postoperative Treatment, in which he points out that methodical insistence on certain postures in postoperative treatment will often enable us to avoid the eventual occurrence of serious complications, especially thrombosis.

There are interesting and practical clinics by Erdmann, Gibson, Hartwell, Albee, Buerger, Heyd, and others, all of which combine to make this a useful volume, both to the student and the practitioner.

LYMPHOID TUMORS.

Lymphosarcoma. Lymphatic Leucemia. Leucosarcoma. Hodgkin's Disease. By L. T. WEBSTER. The Johns Hopkins Hospital Reports, vol. xx, Fasciculus III. Baltimore, 1921.

This monograph contains the histories and a careful analysis of 123 cases of the group mentioned above. It represents an enormous amount of work in an attempt to simplify the classification of these much discussed conditions, and to eliminate a part of the confusion which surrounds them today. One must agree with Ewing that the complexities of the subject of lymphoid tumors depend chiefly upon

the lack of knowledge of their etiology, and until this has been disclosed, such studies as these cannot help greatly in solving the problem of their classification. However, among the few conclusions that Webster draws are the following: "The conditions described are all different manifestations of the same disease, and the term 'lymphadenosis, leukemic or aleukemic' would describe them better and simplify the classification until a definite etiological agent is found. This disease is not a neoplasm, but a direct response on the part of the lymphocytes to a chemotactic influence exerted by the disease causing agent. The presence of this substance in any tissue or organ produces there a local accumulation of lymphoid cells."

THE LOVE OF LIFE.

Back to Methuselah. A Metabiological Pentateuch. By BERNARD SHAW. New York: Brentano's, 1921. Pp. ci-300.

Shaw has threatened this work for many years. In his own criticism of Shaw, written for Frank Harris, he gives warning that he is planning a play which is going to set forth his ideas on creative evolution. Frank Harris found an imago in Shaw and Shaw in turn found his in Samuel Butler. When he wrote his own biography for Harris he felt that Harris was too full of his own ego to give a proper appreciation of Shaw—no doubt he was right. After a careful reading of *Back to Methuselah* and with a comprehensive appreciation of Butler, one feels that Shaw is not an adequate biographer of Butler. Shaw has found his Bible in Butler and there are few living authors who could better champion him. Perhaps if he had not made so great an effort and abandoned himself to fantasy so completely he would have succeeded better. There is plenty of room for the application of Butler, and his sound theory of creative evolution in the fields of reality, to busy Shaw and many other weaker contemporary writers.

There are parts of *Back to Methuselah* which show Shaw at his best, the Shaw we have known and enjoyed in his former plays. He confesses that he has been mediocre in his earlier works, that he has only imitated other mediocrities like Voltaire, Molière, and perhaps the almost forgotten supposedly English playwright called Shakespeare. He tells us that in the past he was only playing, that his near serious efforts were never taken seriously, that his previous efforts dealt with trivialities. Now, he insists, he makes his final effort and if we do not appreciate him our grandchildren may. However, he cannot complain if we read his products and express our most humble opinions.

Can it be that Shaw shows signs of senility? Is he going to join Conan Doyle, Bergson, and the many other gifted men who at some point in their search for truth abandoned themselves to metaphysics when they encountered an obstacle which they could not overcome? Why do they all seek a new form of immortality? Why are they not content with making the most out of reality and their own abilities? Why do they admit defeat in this peculiar way? Perhaps one day an answer will be found when the psychology of senility is better understood. For the present we must be content to

take what they offer and separate the wheat from the chaff.

Shaw has evolved in his concluding scenes a poultry yard myth of creation. Should this form of generation ever come into being it would cause a revision in the technic of obstetrics and in the studies of gynecology. This should be of primary interest to the specialists in these branches of the profession.

New Publications Received.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

THE EMPEROR JONES; DIFFERENT; THE STRAW. By EUGENE G. O'NEILL. New York: Boni & Liveright, 1921. Pp. x-285.

NERVOSE ANGSTZUSTANDE UND IHRE BEHANDLUNG. Von Dr. WILHELM STEKEL, Nervenarzt in Wien. Dritte, Vermehrte und Verbesserte Auflage. Berlin and Wien: Urban & Schwarzenberg, 1921. Pp. x-672.

DIE GESCHLECHTSKALTE DER FRAU. Eine Psychopathologie Des Weiblichen Liebeslebens. Von Dr. WILHELM STEKEL, Nervenarzt in Wien. Zweite Verbesserte und Vermehrte Auflage. Berlin and Wien: Urban & Schwarzenberg, 1921. Pp. xii-490.

DIAGNOSTIK UND THERAPIE DER LUNGTUBERKULOSE. Von HEINRICH GERHARTZ, Professor Dr. med. et phil. Dritte, verbesserte Auflage. Mit sixty-seven teils farbigen Abbildungen und XVI teils farbigen Tafeln. Berlin and Wien: Urban & Schwarzenberg, 1921. Pp. x-296.

THE ANATOMY OF THE HUMAN SKELETON. By J. ERNEST FRAZER, F.R.C.S. Eng. Professor of Anatomy in the University of London and Lecturer in the Medical School of St. Mary's Hospital; Examiner in Anatomy for the University of London. Second Edition, with 219 Illustrations. Philadelphia: P. Blakiston's Son Co., 1920. Pp. viii-284.

INFECTIONS OF THE HAND. A Guide to the Surgical Treatment of Acute and Chronic Suppurative Processes in the Fingers, Hand, and Forearm. By ALLEN B. KANAVEL, M.D., Assistant Professor of Surgery, Northwestern University Medical School; Attending Surgeon, Wesley and Cook County Hospitals, Chicago. Fourth Edition, Thoroughly Revised. Illustrated with 185 Engravings. Philadelphia and New York: Lea & Febiger, 1921. Pp. xiii-500.

THE CLINICAL EXAMINATION OF DISEASES OF THE LUNGS. By E. M. BROCKBANK, M.D. (Vict.), F.R.C.P. Hon. Physician, Royal Infirmary, Manchester; Lecturer in Clinical Medicine; Dean of Clinical Instruction, University of Manchester, and ALBERT RAMSBOTTOM, M.D. (Vict.), F.R.C.P., Hon. Physician, Royal Infirmary, Manchester. Lecturer in Clinical Medicine, University of Manchester. With Illustrations. New York: Paul B. Hoeber, 1921. Pp. viii-88.

NUTRITION AND CLINICAL DIETETICS. By HERBERT S. CARTER, M.A., M.D., Assistant Professor of Medicine, Columbia University, Associate Attending Physician to the Presbyterian Hospital, and Consulting Physician to the Lincoln Hospital, New York; PAUL E. HOWE, M.A., Ph.D., Associate in Animal Pathology, Rockefeller Institute for Medical Research, Formerly Assistant Professor of Biological Chemistry, Columbia University, Nutrition Officer, Camp Kearny, California, and Officer in Charge of Laboratory of Nutrition Army Medical School, Washington, D. C.; and HOWARD H. MASON, A.B., M.D., Instructor in Diseases of Children, Columbia University, New York, Associate Attending Physician to the Presbyterian Hospital, Attending Physician to the Ruptured and Crippled Hospital, New York. Second Edition, Thoroughly Revised. Philadelphia and New York: Lea & Febiger, 1921. Pp. xvi-703.

Practical Therapeutics

CONSTIPATION AND ITS TREATMENT.

By ARTHUR H. HOPKINS, B. S., M. D.,
Philadelphia.

There is probably no symptom more commonly encountered by the general practitioner than constipation. A review of our records will probably show that at least fifty per cent. of our patients complain of it, and in view of its far-reaching effects, other than the symptoms directly attributable to it, it behooves us to leave no stone unturned in the search for its cause and its subsequent correction. Constipation is a condition in which the feces are not passed sufficiently often, or in which defecation occurs daily but the movements are insufficient in quantity. As the normal amount of fecal material varies from 100 to 250 grams, depending on the type of diet, weighing the feces in questionable cases will frequently yield information of value.

SYMPTOMS.

In many cases there are no subjective symptoms; in many more there are sensations of fullness, tension, and abdominal discomfort. At times these sensations are referred to the stomach, as manifested by loss of appetite, belching, nausea, and disagreeable taste in the mouth. Coated tongue and headache are often present, while colicky pains and distention may occur.

It is to be recalled that constipation may occur with one or more daily stools and even diarrhea, a gradual accumulation of fecal material developing all the while. With fecal impaction there may be some escape of material around or through the mass, or at times the irritation of the mass may cause diarrhea.

ETIOLOGY.

To attempt to treat constipation without ascertaining the cause is futile. The first and most important step is to determine the etiological factor or factors, and, in order to do this, a careful history of the patient will throw much light on the subject. By inquiring into what food is taken at each meal, the amount of liquids, the habits of the patient, whether sedentary or active, the first guide for treatment may easily be obtained.

These factors are almost too well known to bear repetition but their repetition seems justified when we consider for a moment the enormous sale of cathartics and purgatives, legitimate and patent, which is carried on by the pharmacist and the manufacturing chemist of today. Let me further emphasize this point by referring to a single drug and showing you the combinations and preparations that commercial exploitation has done for it. I refer to phenolphthalein. Some of the twenty-seven varieties are: Alophen, cholelith pills, ex lac, laxophen, laxine, laxophalen tablets, phenalin, phenolax wafers, probilin prunoids, purgatol, purgella, purglets, purgo, purgolade, purgotin, veracolate and zam zam.

This camouflage for revenue is evidently successful and it will doubtless continue to be so until we

can do more to support the efforts of the medical profession in curbing the advertising of patent medicines in the newspapers and magazines of the country. We may render such support by the proper study of our cases and the refusal to prescribe cathartics when diet and other measures would cure, instead of protract, our cases of constipation. Of importance also is the prescribing of drugs by their official rather than their trade names.

To revert to the question of etiology, several factors deserve our consideration. These are best divided into two groups.

Group I includes actually diseased conditions in which constipation is a symptom, such as the following: 1. Diseases of the stomach, heart, lungs, liver, kidney, pancreas, brain, spinal cord and nervous system. 2. Acute febrile diseases and other diseases confining the patient to bed. 3. Obstruction of entrance of bile into the intestine. 4. Obstruction of the bowel by tumors, stricture, adhesions, and kinks. 5. Malformations, such as dilated colon and diverticula. 6. Enteroptosis. 7. Loss of power of abdominal muscles in emaciated and multiparous women.

Group II is composed of those conditions leading to so-called chronic constipation, the search for and correction of which is so essential for its proper management. Here we have to deal with impaired physiological functions, such as: 1. Retarded intestinal peristalsis, as atony or relaxation of the bowel. Intestinal stasis and enteroptosis may be included in the light of therapy. 2. Spastic constipation, perverted action or enterospasm. 3. Spasm of sphincter.

In short, chronic constipation may be divided into two classes, atonic and spastic. The causes of atonic constipation are: 1. Character and quantity of diet. 2. Lack of physical exercise. 3. Careless habits with regard to stool. 4. Irregularity in living—as traveling, etc. 5. Depressing emotions. 6. Enteroptosis associated with general atony and relaxation. 7. The abuse of cathartics or of large enemas.

On the other hand, the etiological factors underlying spastic constipation are: 1. Nervousness and hysteria. 2. Diseases of the pons and medulla, spinal meningitis and chronic lead poisoning. 3. Debility caused by long continued disease. 4. Sphincter spasm secondary to fissure or ulcer of rectum or reflex from inflammation in neighboring organs, such as the uterus and bladder.

TREATMENT.

This must of necessity depend upon the type, just as the type depends upon the etiology. Regardless of type, however, we have always to bear in mind that the efficiency of peristaltic movements depends upon the normal strength of the bowel muscles, the integrity of the nervous mechanism, the amount of residue in the intestinal contents and the character of the contents as solid, water, liquid, gas and bulk, which are variable in their production of irritation of the bowel. The gases, hydrogen, oxygen and nitrogen, are indifferent, while carbon dioxide,

hydrogen sulphide, and the volatile hydrocarbons stimulate activity.

Sansum calls attention to the three twenty-four hour periods required by the food to traverse the gastrointestinal tract of man. These are: First, to the hepatic flexure; second, descending colon below splenic flexure, and third, rectum and out. This holds for bed patients, but not, as a rule, for those who are ambulatory. He then shows how the type of diet may alter this passage. Probably the simplest measure for estimating the time required for the passage of food through the gastrointestinal tract, in a given case, is to administer a teaspoonful of powdered charcoal and observe the appearance of a black stool.

In the treatment of constipation associated with diseased conditions, as noted in the first group of etiological factors, little will be said here other than to call attention to the fact that the proper treatment of the underlying disease will do much to relieve the constipation. In the management of these patients great care should be taken to avoid rendering them chronically constipated during their illness by establishing the cathartic habit. Diet, water intake, massage in selected cases, the judicious use of an enema and the use of the proper cathartics, only when necessary, would seem to be the more rational method of treatment. Frequent irritating cathartics and purgatives, rendering the bowel more irritable and later more helpless as a result, are in a majority of cases inexcusable.

The daily morning dose of salts (magnesium sulphate, etc.) is insulting to the stomach as it both irritates the mucosa and delays the emptying time, frequently nauseating and depleting the patient and always irritating the intestinal mucosa. There are, of course, indications for salts in selected instances, but I have long felt that the practice was overdone and the indications far too frequently misinterpreted.

With regard to the management of the second group, i. e., chronic constipation, we will first discuss a few general measures. After eliciting the cause by methods mentioned above and eliminating all but the atonic and spastic types, and using the x ray as an aid to diagnosis of type, a hygienic method of living should be established in so far as it is compatible with the patient's occupation. If entirely incompatible, a change of occupation may be essential. Strain and worry should be relieved as far as possible. This holds for both types but especially for the spastic.

Training of the patient, as well as insistence upon cooperation, is very important. Allay anxiety and reassure the patient that if the bowels do not move for a day or so, no harm will be done. Regularity of time for stool at a time when free from hurry is very helpful. The use of a glycerin suppository or the injection of one to two ounces of olive oil by means of a small syringe may afford sufficient stimulation to start a movement and by so doing a normal habit may be reestablished.

DIET.

The human intestinal tract was planned at a time when coarse foods were eaten, while advancing civilization has furnished us with a more concen-

trated diet in which the smoother foods occupy the leading rôle. This change, coupled with sedentary city life, has produced a potent cause for the ever present complaint of constipation. While a part of the stool is composed of the bodies of living and dead bacteria, a part comes from the secretions of the alimentary tract and a far larger part consists of indigestible residue.

Grains eaten in the form of fine white flours and cereals, eggs, milk, cream, butter, fats, oils, meat, fish and sugars are all digested and absorbed and leave little if any residue and yet they form the major part of the diet for many of us. As an illustration, a dog, which on an ordinary mixed diet will have one movement a day, if fed entirely on meat will have one movement in five days. The same holds in starvation. The cell walls of plants are made up of cellulose which is indigestible and forms with the water, which it has the power of holding, the bulk of the normal stool. Bran which is nourishing, agar, vegetables and fruit contain the greatest amounts of cellulose.

Of the vegetables, spinach, cabbage, cauliflower and carrots produce stools nearly equal in amount to the vegetables taken, while fruits produce only about one fourth in bulk. Some of the cellulose in bran undergoes fermentation giving rise to gas and acid both of which are laxative. The dose, to be effectual, should be about two tablespoons twice a day, most pleasantly taken in the form of graham bread or other bakery products, and in purees. It is, of course, contraindicated in excessive digestion of cellulose and consequent flatulence, in gastric motor insufficiency, and in intestinal stenosis.

Agar agar, introduced by Schmidt, is a dried mucilaginous material which adds bulk and softens by retaining moisture. It is most useful where bran is not well borne and is of especial value in spastic constipation and mucous colitis. The dose is from two to four tablespoons used in cereals, in jelly, or added to cooked fruits, but not cooked with them. Olive oil in doses of one to two ounces is both nourishing and laxative; it lessens gastric acidity and retards motility. Its chief indications are spastic constipation, hyperchlorhydria, pylorospasm and peptic ulcer.

In summing up the diet for those patients where too little or too concentrated food has been the cause of the trouble, the introduction of green vegetables, fruit and the reenforcement, if necessary, of bran, agar or olive oil, will do much to relieve the disturbance. Water before breakfast and sufficient through the day should, of course, be urged.

PHYSICAL METHODS.

These are of use to strengthen the abdominal muscles and the bowel, to promote better action and to stimulate peristalsis directly. Massage for selected cases is excellent. Vibratory massage is warmly recommended by some, as is electricity. Gymnastic exercises as an adjunct should be mentioned, as should also hydrotherapy.

INJECTIONS.

Enteroclysis with hot normal saline solution at 110° to 115° for fifteen minutes, three times a week, is of use in obstinate cases, while colonic irri-

gation is valuable in colonic and cecal stasis. The soap and water enema is a simple and effectual measure and one useful, because unpleasant, when training a patient away from the constipation habit. A patient who will use this every third day, or when necessary, instead of using a cathartic, will, as a rule, be particularly careful in carrying out the routine treatment. Klemperer recommends the injection of half a pint of water into the bowel at bedtime, the patient being told to retain it, while Kussmaul and Fleiner employ an injection of sweet oil in the same manner. The amount is gradually increased to eight ounces and is very useful, especially in cases of spastic constipation.

ORTHOPEDICS.

For cases of enteroptosis the abdominal support of one form or another is one of the most valuable measures at our disposal.

DRUGS.

These are mentioned last, because I believe they should be the last to be considered in probably the majority of cases of chronic or habitual constipation. Kemp generally starts the treatment with laxatives, training the patient as to regular habits, etc., and gradually reducing the dose. This, it must be admitted, is in some cases a very useful method. By means of the x ray we are gradually discovering the selective action of certain drugs for certain portions of the intestinal tract, and with further advances in this line more accurate medication will be attained. I refer to the action of podophyllum on the duodenum and aloes and senna on the colon.

Of the more important cathartics a word before closing. Castor oil is comparatively nonirritant and reliable and the quantity of oil that exceeds the digestive capacity is passed through unchanged. It can be so refined as to render it free from smell and taste if protected from the air. Liquid petrolatum is harmless, as a rule, and has its particular usefulness in spastic constipation and in stasis. It lessens irritability, softens feces, but has a tendency to leak. Many varieties are on the market, but by ordering the U. S. P. variety the patient will be saved expense. There is little difference in action between the light and heavy kinds. Cascara in proper doses is exceedingly useful. Senna acting upon the large bowel, is useful in completing the action of a duodenal purgative, such as the mercurials or podophyllum. Rhubarb, the so-called constipating purge, is irritant and has the greatest tendency to succeeding constipation.

I have touched briefly upon some of the most useful cathartics, but it has been my purpose to deal with the treatment of chronic constipation and with that end in view cathartics have been relegated to their proper place, namely, the background. There is no doubt in my mind that there are many types of constipation, as mentioned in the first part of this paper, which call for the judicious use of cathartics, but their discussion lies beyond the scope of this paper.

Permit me to emphasize two points in closing and they are, first, cathartics should not be used where other measures will suffice, and secondly, purges should not be used where laxatives will do.

1726 PINE STREET.

A NEW DUODENAL TUBE FOR THE STUDY AND TREATMENT OF DISEASES OF THE DUODENAL AND BILIARY PASSAGES.

(Preliminary communication)

By L. WINFIELD-KOHN, M. D.,
New York.

The important rôle that the duodenum plays in disease of the alimentary tract impels every student of gastrointestinal disturbances to centre his attention upon this organ and the neighboring biliary apparatus whenever patients complaining of symptoms of indigestion present themselves for study.

Disease of the duodenum is of rather common occurrence; in fact, many regard the duodenum as being the seat of ulcer more often than the stomach. It may also be emphasized that diseases of the gall-bladder, gallducts, liver and pancreas are more common than many of us have suspected. The reason why affections of these organs have been found so frequently within recent years is that our methods of investigation of the duodenum have become more practicable and efficient, in consequence of which diseased conditions are more readily recognized. It would be unreasonable to suppose that diseases of these organs were less prevalent in former years, but it would seem logical to presume that because of our lack of knowledge at that time many of these ailments were overlooked.

When we consider the relationship of the duodenum to its neighboring organs from anatomical and physiological viewpoints, we can readily appreciate the reasons for the formation of disease at this site. We can readily understand the possibility of a transference of disturbance affecting the many functions of the stomach to the duodenum. The results of disturbed gastric function such as hypersecretion or hyposecretion or disturbed motility may in many instances contribute to the creation of duodenal disease. In a similar manner we can presuppose the establishment of disease of this organ from primary disturbance in the adjoining organs of the biliary system, and we may also assume that primary disease in the duodenum may cause disease in the organs of the biliary tract.

We cannot dispute the fact that the duodenum is open to the development of disease from other sources through the blood or lymphatics as mediums of conveyance. This same process of reasoning applies to disease in the organs of the biliary system. The more or less constant abuse inflicted upon the organs of alimentation through dietary indiscretion also invites disease of the duodenal mucosa. Mechanical interference, as in instances of high fixation of the duodenum by the ligament of Treitz while the rest of the small bowel and stomach are profoundly ptosed, will also encourage duodenal disease. Excessive chemical stimulation of the duodenal mucosa by hypersecretory gastric material may also incite disease of the duodenal lining, and the same may be said of irritation by the pancreatic and biliary secretions.

Now that we have admitted the frequency of duodenal disease and appreciated the reasons for its occurrence, we also immediately become impressed

with the great need of recognizing the disease or disturbance when it exists. Many mechanical contrivances, such as the Einhorn, Jutte and other tubes, have been devised for the purpose of rendering this cavity accessible to study and treatment. Palefski recently laid stress upon the use of the duodenal tube for the purpose of outlining the duodenum. Lyon came forth with his method which aims at a better understanding of the pathology of the biliary system and which consists of introducing magnesium sulphate solution into the duodenum, in consequence of which the sphincter muscle at the papilla of Vater relaxes and biliary material enters into the duodenum.

The new tube that is introduced here has been designed with the object of isolating the duodenum from the remainder of the alimentary tract. By temporarily separating this portion of the tract from the remainder of the bowel and stomach, certain detailed studies can be carried out that are otherwise impossible. As a result, the duodenum and its contents are under our immediate control, and although as a result of the temporary isolation there may be some slight interference with duodenal or gastric physiological activity, I hardly look upon such disturbances as objections to the use of this instrument. Of course, further experience with the use of this tube will bring out both its good and bad features.

The instrument consists of a hollow tube which embraces in its cavity two separate hollow tubes of decidedly smaller calibre and a columnar hollow space. The tube is widest down to its pyloric mark and below this point is much narrower, owing to the fact that from here down it contains only two avenues of communication. The lowermost avenue communicates with a rubber bag that can be sufficiently dilated with air to approximate the circumference of the duodenum, thus cutting the duodenum in its lowermost or distal portion off from the rest of the bowel beneath. Above, at a certain point corresponding to a position within the stomach just above the pyloric ring, another air bag arrangement exists, to be ballooned out so as to hug the circumference of the lowermost pyloric part of the stomach just proximal to the pyloric ring; or, if this bag also is allowed to pass into the duodenum, it may be blown up and drawn upward so as to hug the duodenal side of the pyloric ring. Between these two outlets, within the duodenum, a small opening in the tube communicates with the duodenal cavity, and through this opening the duodenal contents can be aspirated or, instead, the duodenum can be filled. Above, outside of the mouth, we can connect with each tubal compartment separately. Both air spaces may be filled with air while the duodenal space is managed according to our judgment. The tube in its widest diameter is quite small and slightly longer than the ordinary duodenal tube, and is marked off so as to give us an idea of its position in the digestive tract. Slight improvement from time to time may render this contrivance still more serviceable. By an elongation of the distal end of the tube we may be enabled to make studies of the jejunum and the gastrojejunal communications of gastroenterostomy patients.

Another similar tube arrangement, devoid of air bag attachment near the pylorus, has also been made, and with this I am also making studies of the duodenum. I am looking into the effectiveness of the pyloric contraction about the tube without the use of the supportive closure influence of an inflated air bag at or above the pylorus.

Both of the tubes described above are modifications of the duodenal obturator and sectional intestinal examiner tubes, described by Einhorn (1) but not advocated by him for study in the same detail as indicated below. To Einhorn, however, belongs the credit of having first delved into the innermost recesses of the smaller bowel.

By thus isolating the duodenum, numerous possibilities for the use of this instrument loom forth very forcibly.

1. Its greatest immediate use will probably be for studying the outline of the duodenum in its entirety and the nature of its association with the stomach through fluoroscopic or radiographic methods. By more adequately filling out the duodenum, our knowledge of the anatomy and physiology of the duodenum may in the future become considerably enhanced. By the process of alternately cutting off and supplying air to the rubber bags at estimated intervals, the motor activity of the duodenum or jejunum may be better appreciated. The effect of muscular contraction upon the artificial air bubbles may lead us on to some conclusions, and the employment of both the prone and upright positions during the course of the examinations may also aid in clarifying matters.

2. We may even contemplate going a step farther, since we feel that we can relax or open Oddi's sphincter at the papilla of Vater and make an effort to fill up the gallducts and pancreatic duct with either air or a harmless yet impenetrable rendering solution so that by shadows the x ray may delineate the biliary system and pancreatic ducts. By filling up the duodenum above the blockade it may be possible to dam such a solution back up through the previously relaxed sphincter.

3. From the viewpoint of biliary system study, we may, through isolation of the duodenum, gain a better idea of the true effect of magnesium sulphate and other medicaments upon the biliary tract. A more adequate appreciation of the amounts of bile eliminated, the quality of the biliary and pancreatic secretions and the pathological elements present in these parts will be attained.

4. More satisfactory means of directly applying medication to disease in the duodenum may be practised, and the treatment may be continued in an uninterrupted manner for a period long enough to obtain better results from the viewpoint of healing effect upon ulcer, inflammation, etc. The probability of directly treating diseases of the bile tract through this contrivance does not seem remote.

5. By employing a tube, the distal portion of which is prolonged, studies may be made of the gastrojejunal stoma and of lesions at this area, especially through fluoroscopic and radiographic means.

6. With this tube as a medium, we are now attempting to gather direct evidence of conditions existing within the duodenum, pancreatic and biliary

tracts in a manner that has never been employed before to our knowledge.

I am greatly indebted to Mr. A. E. Pfarre for his kind suggestions and valuable aid toward the development of these instruments.

SIMPLE METHOD OF REFILLING CONTAINER FOR ADMINISTERING FLUIDS.

BY JACOB BUCKSTEIN, B. S., M. D.,

New York,

Consultant in Gastroenterology, U. S. Public Health Service.

This container consists of a nonbreakable vacuum bottle, a thermometer and a graduated gauge. The vacuum bottle conserves the temperature of the contained fluid. The thermometer is so arranged as to register the temperature of the fluid as it makes its exit. By means of the graduated gauge, the level of the fluid within the opaque container can be determined, and also the rate of flow. The container

connected and at its end a glass tube with funnel shaped top is inserted. The tube is approximately the length of the container. The fluid may then be poured in from the flask. The level of the fluid within the container will rise to the same height as the level of the fluid within the glass tube. After the container has been filled to the desired level, the glass tube is removed and the rubber tubing reattached to the projection. By releasing the clamp the fluid will again flow through the rectal tube.

Continuous or even intermittent proctoclysis is thus simplified, through the easy manner in which the container may be refilled. The same principle may be employed when the apparatus is arranged for the administration of fluids intravenously, by hypodermoclysis, and for administering irrigating fluids.

Treatment of Mucous Colitis.—G. P. Hamner (*Virginia Medical Monthly*, March, 1921) recommends daily colonic lavage with a solution of sprudel salts as the best measure for removing mucus and relieving toxemia in this disorder. To this may be added, on occasion, large doses of castor oil by mouth to facilitate passage of the mucus. The enemas should be taken with the patient on the left side and hips elevated slightly higher than the shoulders, and the solution should be as hot as can be comfortably borne. Transduodenal lavage with four per cent. sodium sulphate solution has been used of late with reported success. There should be insistence on regularity of bowel movements, but overuse of enemas and colon irrigations is to be forbidden. The diet must be ample. Use of bran, coarse foods, and too much fruit should be discouraged at the start, a mild laxative agent such as liquid petrolatum, cascara agar, phenolphthalein agar, or small doses of magnesia being preferable. If these do not suffice, cascara, rhubarb, aloes, senna, or compound licorice powder may be added. Retention overnight of four to sixteen ounces of cottonseed or olive oil is also valuable. If, after long and faithful trial, these measures fail to overcome stasis and toxemia, surgical treatment is to be seriously considered. Where hemorrhoids interfere with treatment, nightly instillation into the rectum of sixty mills of warm olive or cottonseed oil with a soft rubber ear syringe is advisable, but only until the patient is able to have them removed surgically. The diet should, at the outset, generally be of the bland, lactofarinaceous type. Coexisting appendicitis, cholelithiasis, adhesions, bands, or pelvic disturbances should be surgically corrected. Occupation, recreation, and rest in proportions should be advised and introspection strongly discouraged. Change of scene is of great help. In attacks of colic, the indications are to relieve pain and neurotic symptoms and promote evacuation of mucus. The measures appropriate are rest in bed, one half to one dram of bromide, a hypodermic of atropine, the hot water bag, electric pad stupes, morphine very carefully, a large dose of castor oil, and colon irrigations with warm soda solution. A combination of castor oil by mouth, codeine and atropine hypodermically, and colonic lavage is often followed by relief and sleep.

has the capacity of approximately one litre. After it has been emptied of fluid, I have devised the following simple method of refilling it, as often as may be desired, without the necessity of inverting the container, and removing the cover and stopper.

Ordinarily the piece of rubber leading from the fluid outlet tube is attached at the projection marked I, as indicated by the dotted line in the accompanying cut. In refilling, this piece of rubber is dis-

Proceedings of Societies

AMERICAN GASTROENTEROLOGICAL ASSOCIATION.

Twenty-third Annual Meeting, Held in Atlantic City, N. J., May 3 and 4, 1920.

Dr. FRANKLIN W. WHITE, of Boston, First Vice-President and Acting President, in the Chair.

President's Address.—In the absence of the president, Dr. Thomas R. Brown, of Baltimore, Dr. Franklin W. White, of Boston, the first vice-president, delivered the annual address.

Diaphragmatic Hernia Diagnosed During Life.—Dr. MILTON M. PORTIS, of Chicago, said that only a small number of these cases were diagnosed during life, most of them being found at operation or autopsy. The cases were either congenital or acquired, trauma being a factor in the latter—especially war injury—and were not so rare as was ordinarily believed. These hernias most frequently occurred in the congenitally weak places in the diaphragm, and they occurred fifteen times as often on the left as on the right side, this probably being due to the protective action of the liver. The organs most commonly found in the hernia were the stomach and colon. At times, however, the small intestine, the liver, spleen, and all the mediastinal viscera might be found in the hernial sac. There were no pathognomonic symptoms. In some cases the symptoms pointed to the gastrointestinal tract, and in others the symptoms pointed to the chest. The symptoms, he said, depended upon the size of the hernial protrusion and its location. When the hernia was large, one found tympany where there should be lung resonance; or, when there was fluid, one found dullness where resonance should be. The diagnosis was largely made by the x ray. The fluoroscope made it possible to demonstrate the condition easily. For the radical cure of these hernias, surgery was the only method of treatment. Small hernias that gave no symptoms required no treatment. In mild cases, the treatment might be purely palliative, along simple lines. When, however, the symptoms were persistent and resisted ordinary medical measures, there was only one treatment—surgery.

Dr. SEYMOUR BASCH, of New York, said that Dr. Portis had correctly stated that the diagnosis of diaphragmatic hernia had advanced considerably in the last decade, mainly through the aid of the x ray, and, probably from the fact that increasing knowledge had directed attention to its recurrence, more cases had been discovered, and not because the condition was of greater frequency than formerly. Previous to the use of the x ray, the diagnosis had sometimes been made during life by clinicians, and, of course, it was considered a condition of great rarity.

The diagnosis of diaphragmatic hernia was very easy in modern times, as hinted by Dr. Portis, when one had a pronounced, an extreme case; but when there was a small hernia, such as might be produced

by a stab or a pistol wound, or by spontaneous rupture of the diaphragm, the difficulty was much greater, and could be made only through repeated and careful examination.

The two points that were important to remember regarding x rays were that, while one saw the upper line of the stomach, it was not, as Dr. Portis pointed out, the line of the diaphragm. The line of the diaphragm in a true hernia was broken, and one got the contrast with the other side by comparison. The line of the stomach was a large, pronouncedly white line, and could be diagnosed readily, even without the stomach being filled. A second point of importance in the differentiation between either the relaxation of the diaphragm in congenital conditions and true hernia was that in watching the fluoroscope and having the patient breathe deeply, the abdominal organs, in true hernia, usually moved upward; whereas, in congenital relaxation, the respiration pushed them down. From the x ray viewpoint, this was more important through the fluoroscope than through the x ray plate, because with the fluoroscope one could, by changing the position, notice the line of fluid and see the organs almost as well as with the plate. Among the physical signs there were two or three that were of importance, one of which was not mentioned by Dr. Portis, namely, displacement of the heart. Almost all of these hernias were on the left side, and, as a result, the stomach being prolapsed, the heart was pushed to the right.

Elevation of the Left Diaphragm.—Dr. FRANKLIN W. WHITE, of Boston, presented lantern slides of an unusual case of elevation of the left diaphragm (eventration), with inverted stomach, stomach, as part of the discussion on Dr. Portis's paper on hernia. The patient was a man sixty years old, a typical club man, well preserved and goodlooking; he had used alcohol freely, and had been free from gastrointestinal symptoms until about a year and a half ago, the sole exception to this being that if he ate a big dinner, he almost invariably vomited it up. The other unusual thing about the case was that during the last ten years the patient habitually gulped up some fluid about ten minutes after a meal. In the past eighteen months he had had several serious attacks of gastric pain, and had had two serious hemorrhages from the stomach. Several x ray plates of the patient's stomach were presented, one of the most important showing the extreme differences in the position of the stomach at different times. Dr. Portis found that when the patient had his worst attacks, the stomach was above the diaphragm, and that when it was going along relatively well, the stomach was three fourths below the diaphragm. He also got it in several intermediate positions.

Concerning the diagnosis, he said the important thing was to distinguish it from a highsided left diaphragm, which he thought was a better term than eventration. The highsided diaphragm was not

a surgical condition; eventration was. Physical signs did not distinguish the two things. One got the splashing associated with air in the lower part of the chest in both conditions, and could make the clear diagnosis only by x ray examination. Some things had been put down as diagnostic that were not of great value, in his opinion. Respiratory movement on both sides did not help in distinguishing high-sided left diaphragm from hernia. The hernia might move up and down and the diaphragm might be immobile. The movements must be equal with respiration and must be in the normal direction. The domeshaped line was considered characteristic of the left-sided diaphragm. In the right kind of hernia, one got a symmetrical domeshaped line, even in hernia. The so-called paradoxical respiration, the right side going down and the left going up, was not a good sign, because it was too rare to be a good diagnostic sign.

Diagnosis and Treatment of Recurrent Cholecystitis.—This paper was by Dr. MAX EINHORN and Dr. WILLY MEYER. Dr. Einhorn said he would not give in full his portion of the paper, but would pick out only a few points to discuss. He said that there existed two types of chronic cholecystitis, 1, those with symptoms of a distinct biliary colic, and, 2, those with definite abdominal disturbances. A diagnosis of chronic recurrent cholecystitis could frequently be made, even when stones were absent, by the symptom present, in conjunction with a direct examination of the bile. When, in such case, he found turbid bile, he operated. When operating for cholecystitis, a chronically diseased gallbladder should be excised, even if no stones were found in the affected organ. If the contents were found to be turbid, the gallbladder should be rejected. In those cases of cholecystitis where there was protracted fever and in which there was a leucocytosis and perhaps a polynuclear increase, operation should be performed, especially if the bile in the duodenal contents was found to be turbid.

As regards the treatment, there was no doubt about the thoracic method's being better for the repair of the hernia; but it had one drawback, and that was that it was impossible to inspect the abdomen and see whether there was any injury to the organs. Many operators use both: the thoracic first, and later through the abdomen below. A surprisingly large number of good results had accrued in the last six years from operative procedure, compared with the previous lamentable results.

Dr. Meyer discussed the subject from the viewpoint of the surgeon. He said that whenever a case of recurrent cholecystitis was presented for treatment, one naturally thought of the stomach, the duodenum, the pancreas, the gallbladder, and frequently the appendix or the kidney. Other abdominal troubles often arose. So far, it had not been found, since the introduction of the x ray and the cholesterol treatment, that the findings had greatly improved the means of diagnosis, although progress had been made in that respect. Nearly fifty per cent. of the cases showed stones in the gallbladder, but he did not believe that at that time the x ray was able to show a nondistended, nonthickened gallbladder on the plate. Cholesterol had been found

to be unreliable as a method of diagnosis. When asked to operate in such cases, an examination of the duodenal contents had been made. In every case in which the gallbladder cannot be felt and the symptoms do not point to gallstone colic, examination of the duodenal contents was pretty nearly sure to reveal turbid bile, cholesterol, bilirubin, etc., even if no stone was found at operation. Dr. Einhorn had preserved the turbidity and the color of the bile artificially, so that one might compare it with the findings during operation. Naturally this could be done only by aspirating the gallbladder. While aspirating, greenish black and brown turbid bile had been found, which, up to the present time, had been considered as an indication for the removal of the gallbladder.

Dr. Meyer found, in cases where operation was refused for one reason or another, that the symptoms recurred eventually and for the patient's lifetime, up to the time that the gallbladder was removed. Reports of sterile bile in such cases had been received frequently, and one had begun to ask whether the right thing was being done. On thinking of what might produce the sterile bile, one realized that bile of itself would, in a little while, destroy the contained microorganisms. It was an anaerobic condition. The laboratories made their studies not in an anaerobic way. Then there might be a certain number of bacteria in the bile at times, and at other times none; the bit of bile examined might contain bacteria, and other portions of the bile, none.

The second question was, How does normal bile in the gallbladder really appear? In other words, was a greenish black or brown bile, slightly turbid, always anaerobic? He believed that it was, because since they had started they had adopted the following procedure in their investigation: the instant the person in the laboratory received the bile from the gallbladder which had been operated upon, he spread it out on the bouillon, at the operating table. He then bisected the gallbladder transversely, using the lower portion and the cystic duct for culture and the upper portion for pathological examination. In the majority of their cases, they had found that the gallbladder wall, as such, contained the bacteria; and they recognized the fact that these bacteria might now and then enter the bile and reinfect it. They considered this an indication for removal, because they could not see how such a gallbladder could, by internal means, recuperate itself. It had to come out. Therefore, it was thought that cholelithiasis was a more frequent disease than heretofore considered.

With the x ray they could exclude gastric and duodenal ulcer, where it was shown that the pancreas was discharging normal ferments; but they found this turbid bile with cholecystitis, without stone. It was more common in the male than in the female. Women almost always had the stone in connection with the cholecystitis. In one case they found a stone that had ruptured the gallbladder so that the bile was running down from the liver. A condition like that, this method could not show; but it could show turbid bile.

(To be concluded.)

Miscellany.

Cholecystostomy and Cholecystectomy.—Frank D. Moore (*Surgery, Gynecology and Obstetrics*, July, 1921) asserts that we may summarize the end results of cholecystectomy as compared with those of cholecystostomy as follows.

In general, cholecystectomy is the operation of choice in all cases, except where general debility, serious complications, such as abscess, peritonitis or previous extensive adhesions make removal too dangerous or prolonged an operation. In these cases, cholecystostomy with possible later cholecystectomy, may be done with advantage. It has been proved by numbers of cases and observations by various authors, that a removal of the gallbladder is not, in itself, detrimental to the future health and well being of the patient. Why, then, permit the patient to face the risk, not only of possible, but of probable recurrence of trouble, with the necessity of a future second and more difficult operation, when, in the hands of a careful surgeon, a total removal of the offending organ may be done with but slightly greater expenditure of time and with but little more immediate risk to the patient?

Judgment in the selection of cases for removal, early diagnosis and early operation, all make for the choice and ultimately vastly more satisfactory results of cholecystectomy. The value of this method of treatment for appendicitis is unquestioned, and it seems as logical to follow this same procedure in the case of a similarly affected gallbladder. A diseased appendix is obviously of no use and is manifestly a source of danger. Is not a functionless and diseased gallbladder to be regarded in the same light? The diseased gallbladder has also come much into the limelight, of recent years, as a focus of infection for various forms of arthritis, anemias

and general constitutional disturbances, and many removals of the gallbladder have been followed by marked improvement in the general bodily metabolism and welfare. It would seem, then, that cholecystostomy may well be regarded only as a makeshift or temporary resort, where conditions are such as to contraindicate the performance of a truly remedial operation, and that cholecystectomy may be accepted as the operation of general choice.

Foreign Bodies as a Cause of Appendicitis.—S. A. Mahoney (*Boston Medical and Surgical Journal*, February 3, 1921) has made quite a study of the literature on this subject, and finds that pins are the foreign bodies most frequently found in the appendix. The cases are rare, only forty pins in 160, or possibly 228 years, if the case of Ruysch in 1691 is considered the first. Only eighty-six cases of true foreign bodies were found in the literature. Cases of true foreign bodies range from 0.2 per cent. to 12 per cent. among American observers, while foreign observers make the percentage higher—as high as fifty per cent., probably because they classify fecal concretions as foreign bodies. The pin generally lies quiescent in the appendix for a long time, and the attack causing operation generally is acute. The pin may enter by head or point, and lie transversely or parallel to the axis of the appendix. The appendix is generally perforated by the point of the pin and abscess formation is generally present, with metastatic abscesses of the liver rather common. Pins occur more often in males than in females, and most frequently in children under ten years of age.

Chronic Afebrile Appendicular Jaundice.—C. P. Caplesco (*Bulletin de l'Académie de médecine*, March 29, 1921) describes an afebrile chronic jaundice of mild grade due to toxemia from unrecognized disease of the appendix. The patients suffer from digestive disturbances of various sorts, such as epigastric pain and weight after meals, capricious appetite and irregular digestion, and sometimes nausea; other patients are constipated and suffer from migraine. The icteric condition is marked merely by a varying degree of discoloration of the conjunctival cul-de-sacs, associated occasionally with a yellow color of the bulbar conjunctiva. Careful examination of the region of the appendix in over fifty cases revealed tenderness in this area. By beginning the examination of his patients with a search for this discoloration of the conjunctiva, or conjunctival sign, the author has been led to detect appendicitis in individuals who did not suspect that they had any appendiceal trouble. In all cases subjected to operation on the basis of the conjunctival sign obvious appendiceal disease was found—e. g., an enlarged, congested appendix containing bloodstained material or fecal matter, calculi, and parasites, with constant dark areas and ulcerations of the mucous membrane beneath such foreign bodies and a fibrous thickening of the submucous layer. The discoloration of the conjunctivæ is ascribed to toxic material formed in the diseased appendix, absorbed and carried to the liver, where it causes enough disturbance of the hepatic cells to induce a mild toxic icterus.

Pseudotabetics and Their Reeducational Treatment

By PIERRE KOUNDJY, M. D.,
Paris,

Late Chief of the Reeducation Services at the Salpêtrière, and of Physiotherapy at the Val de Grâce.

It is often simple enough to mistake a pseudotabetic for a genuine case of tabes, for the symptomatology in both instances is frequently very similar. Thus one finds incoordination of movement of the lower limbs and ataxia of the upper, Romberg's sign, absence of patellar and Achilles tendon reflexes, anesthesia, analgesia, delayed transmission of impulses, lightning pains, gastric crises, visceral crises, amblyopia, muscular pains, and, occasionally, a disturbance of the reaction of the pupil. These symptoms may be encountered in pseudotabetics, either isolated or in groups of two, three or several signs together, and thus suggest the presence of a true locomotor ataxia of Duchenne, of Boulogne. Occasionally, this similarity extends even to a confusion in the findings of morbid anatomy. Thus, Tuzek, of Vienna, has published reports of four cases of pseudotabes with records of autopsies and serial sections of the spinal medulla, in which one can trace sclerosis of the whole length of the posterior columns similar to the lesions in true tabes.

In spite of this, pseudotabes is a pathological entity easily distinguished from true tabes on account of its etiology and, especially, of its course. According to Professor Déjérine and Dr. Thomas pseudotabetics are characterized by their tendency to complete cure, by tenderness on pressure of muscles, and by the absence of the Argyll Robertson pupil. Further, they can be distinguished by the different topographical distribution of anesthetics, "which here diminish from the distal end towards the root of a limb, whereas in tabes they always show a radicular distribution" (1).

Professor Déjérine, who published his first two observations on pseudotabes in 1882, has termed this affection neurotabes or peripheral tabes, thus indicating the polyneuritic origin of the disease. We have noted above that even medullary lesions may exist in cases of pseudotabes, as demonstrated by the observations of Tuzek. There are also varieties of pseudotabes which show at the same time medullary and peripheral lesions, such as in those due to diabetes. In the majority of cases pseudotabetics also present psychic disturbances in

the form of phobias in addition to two or three signs of tabes, such as Romberg's sign, lightning pains and disturbances of sensation, or the loss of reflexes. The dominating obsession is the morbid fear of walking. Basiphobia is the psychic element characteristic of pseudotabetics.

Further, there are the phobia of space, agoraphobia, and the fear of standing alone and unsupported, stasiphobia. We have known a pseudotabetic who, on finding herself suddenly isolated from the crowd with which she had been crossing the entrance hall of the Saint Lazare Station, experienced great difficulty in walking. When surrounded by people, she could manage to reach the platform, but when isolated, she could not move and had to wait for the propitious moment when she could join the company of others, before she was able to continue on her way. It has to be noted in this connection that the same psychic condition may be encountered in cases of true ataxia. However, in the latter it assumes a graver aspect, for this complication considerably increases motor incoordination and finally renders progression quite impossible.

It has been stated that the motor incoordination of pseudotabetics does not resemble the locomotor ataxia of Duchenne, of Boulogne. Nothing could be more inexact. Though in some cases of pseudotabes the motor incoordination approaches the type of polyneuritic ataxia, characterized particularly by "steppage," yet, in the majority of cases it is, so to speak, a copy of the ataxia found in true tabes. The walk of pseudotabetics is precipitated, jerky, staggering, hesitating, and spasmodic in a fashion equal to that of a good many true tabetics. These manifestations show the closest resemblance in the case of a pseudotabetic whose symptoms suggest an early stage, or the first degree of locomotor ataxia. There we find the same inequality of steps and the same absence of rhythm in the walk and the unilateral predilection of spasms. Dr. Berbez has reported a very curious case of false tabes with severe motor disturbances of the upper limbs. "The patient was unable to carry to his mouth a glass filled with water without spilling the contents" (2). Quite recently Professor Déjérine presented at his

interesting Tuesday demonstrations a girl, eleven years old, who suffered from peripheral tabes of infectious origin, probably diphtheria. She was affected at the same time with pronounced motor disturbances of the upper limbs, diplopia, and very extensive sensory changes.

The motor disturbances of the lower limbs may become so troublesome in pseudotabetics that they are rendered quite helpless. Fourteen years ago, at Charcot's clinic, we had under our care a pseudotabetic with complete lack of control of the legs. The patient was confined to his bed for four months without being able to hold himself upright for an instant. However, reeducation exercises trained the patient to walk well and unsupported at the end of a month's treatment. In Dr. Berbez's case the paraplegia of the lower limbs was complete. Thus, motor incoordination of pseudotabetics may present all the phases of tabetic ataxia ranging from commencing to final paralytic ataxia.

Romberg's sign is the second symptom of tabes dorsalis which is found again and again in pseudotabetics. Incidentally, it may be mentioned that the pseudotabetic usually discovers the presence of his illness by the impossibility of standing upright in the dark or with his eyes closed. This sign is rarely absent, and, whatever the cause of the pseudotabes, it can be noted with ease. Occasionally, it is necessary to let the patient stand on one foot in order to demonstrate it clearly.

The pains in pseudotabes differ in character from the lightning pains of true tabes. They seldom occur in the form of regular crises, and, often, they are only of short duration. They may be localized, as in true tabes, in the lower limbs, in the chest, or they may assume the form of unilateral or bilateral sciatic pains. Sometimes they persist for long periods. The chief characteristic feature, however, is their complete cessation with the disappearance of the other tabetic symptoms.

The sensory disturbances in false tabes also differ from those found in true tabes. They have an irregular topography, being localized sometimes in one limb, sometimes in both at the same time, but only rarely do they present the symmetrical form shown by the sensory affections in true tabes. They are situated distinctly at the periphery and diminish steadily as the root of the limb is reached. They are, therefore, differentiated from the sensory disturbances of true tabes by the absence of the radicular arrangement. In a few instances one meets with plantar anesthesia and the "cotton wool sole" of the tabetic.

Delayed transmission of impulses is a relatively frequent phenomenon in pseudotabetics, especially if neurasthenia is present. Absence of the patellar reflexes is not a constant phenomenon in pseudotabes, but in many cases it exists together with Romberg's sign and motor incoordination. In other cases one finds, on the contrary, that these reflexes are exaggerated. Generally speaking, return of reflexes is the rule here, whereas their abolition is permanent in cases of tabes dorsalis. The gastric and visceral crises of pseudotabetics have not the same severity as in true tabes; they are never continuous. Among the visual disturbances of pseudotabes

diplopia is only rarely met with; and, if it does exist, it is only partial and often very faint.

It is clear from the preceding that cases of pseudotabes may occasionally resemble so closely cases of tabes dorsalis, especially when locomotor ataxia exists, that confusion may arise in spite of all endeavors. However, if investigations are persisted in with patience, one cannot fail to establish the correct diagnosis of the affection. This has called forth the statement by Professor Raymond in his masterly dissertation on the Diseases of the Nervous System, that pseudotabetics are differentiated from true tabetics by the evolution of the symptoms, the rapidity of their development, and their usual curability. In fact, a pseudotabetic recovers always and in a very short time, relatively speaking. Relapses may occur and the same manifestations recur as before, but in the end a definite and complete cure is effected. A true tabetic may improve, often to a notable extent, but he will always retain the stigmata of the affection for his whole life.

Among the etiological causes of pseudotabes we may quote intoxications, such as alcohol, lead, copper, arsenic, nicotine, carbon bisulphide, ergot, and diabetes; infections, such as diphtheria, smallpox, scarlatina, syphilis, and dysentery; hysteria, neurasthenia, overwork, and exposure. There are also cases of pseudotabes of obscure origin. The list given above makes it unnecessary to discuss each etiological form of the disease. We shall only deal with syphilitic pseudotabes, for syphilis may be the cause of this affection, just as it is responsible for the great majority of cases of tabes dorsalis. Lamy (3) in his remarkable work on syphilis of the spinal cord, presents the observations of several authors on cases in which cerebrospinal syphilis represented the clinical picture of pseudotabes, identical with that of tabes dorsalis, with ocular paralysis, lightning pains, visceral crises and incoordination of progression. This author also quotes a similar observation of Fournier and Dieulafoy in a case of tabes where the symptoms of cerebrospinal syphilis were manifested by gradual paralysis of the lower limbs, lightning pains, loss of patellar reflexes, and disturbances of progression; in other words, by the phenomena of syphilitic pseudoparalysis.

Claude reported to the Neurological Society in 1908 the case of a man, forty-one years old, who had acquired syphilis five years previously. Four years before examination the patient experienced weakness in his lower limbs and marked lightning pains. Under the influence of mercury, prescribed by Claude, the latter symptoms disappeared completely. A few months later difficulties arose in the control of micturition. On examination Romberg's sign, recurrence of motor incoordination, and paresis of the lower limbs were discovered. The patellar reflexes were present, and the pupils were normal. A second vigorous mercurial treatment was instituted and, once more, all symptoms disappeared. The patient died two years later of phthisis. At the autopsy a few strands were found to be affected with syphilitic meningitis and with slight medullary degeneration; however, no trace of a lesion of the posterior cords could be discovered. Undoubtedly then, this was a case of syphilitic pseudotabes.

We have seen above that two causes are necessary for the production of pseudotabes: 1, the true etiological cause, such as intoxication or infection, and 2, the predisposing cause—the psychic condition of the patient. Pseudotabetics are above all neurotics, a fact explaining to a certain degree the characteristic aspect which tabetic symptoms assume in these cases. This further serves to explain the rapid development of the illness as well as the complete cure and the disappearance of symptoms.

The therapy of pseudotabes must, therefore, be divided into two groups: the first aims at removing all causes of intoxication, infection, or overstrain. The patient should be placed under the best hygienic conditions and submitted to an appropriate dietetic régime, and all therapeutic means should be applied, which act internally on the specific causative agent: potassium iodide, arsenic, mercury, benzonaphthol, aspirin, etc. The second group comprises all external measures, or, in other words, all physical agents which act on the symptomatology of the affection and on the psychic condition of the patient at the same time. The measures referred to are psychotherapy and all agents of physiotherapy: isolation, direct and indirect suggestion, hydrotherapy, electrotherapy, radiotherapy, thalassotherapy, crenotherapy, and exercises.

We shall refrain from discussing the special indications of all these physical agents for the treatment of pseudotabes. But we shall dwell at some length on the physiotherapeutics of pseudotabes and, more especially, on its treatment by massage and reeducation of movements, which we consider the method of election in these cases. Experience has shown that physical agents act on the patients in question by direct action on their motor disturbances, and by indirect suggestive effect on their psychic troubles. Massage stimulates the circulation in a large number of pseudotabetics and counteracts the destructive influence of the causal etiological agents. Thus in many cases it suffices to massage the paretic muscles in order to arrest the paresis and to prevent in this way the onset of muscular paralysis. The ordinary principles of massage must be observed: that only the muscles in a state of hypotonia require treatment. Mechanotherapy and gymnastics can be frequently utilized as complementary agents. Alone, reeducation of movements forms the pivot of the kinetic treatment of pseudotabetics; for reeducational exercises take the principal share in correcting the motor disturbances of these patients and in influencing their psychic condition. The choice of reeducational exercises is of great importance in this connection. All the different series of exercises should not be gone through repeatedly, otherwise they might be discredited in the eyes of the patient. He must not be allowed to come to the conclusion that his exercises are too simple and, consequently, not suited to his condition; neither should his exercises be too difficult so that his enthusiasm gets chilled by the impossibility of their execution. The nature of the exercises at the commencement of the treatment of pseudotabetics vary; thus, if in one case we begin with walking exercises, in another we start with those aiming at standing upright, equilibrium of the

trunk, or stability. If a pseudotabetic is in a stage resembling locomotor ataxia of the first degree, we begin at once with exercises on the graduated floor or with a chair, in other words we aim at regularizing his steps or at teaching balancing of the chest. And often we can note that such exercises succeed in securing further results, such as reduction of the basis of support or progression on the horizontal ladder. In the rare cases of pseudotabes with advanced weakness we commence reeducation by exercises in the sitting position, whereas with true tabetics the prone position is adopted.

Whatever the nature of the exercises chosen, they are always arranged in rapid and almost uninterrupted progression, so that a period of one or two weeks enables the pseudotabetic to regain his coordination completely. Just as much depends on his psychic condition. In this connection we must make use of psychotherapy, verbal assurance, reasoning, suggestion. All these measures together and reeducation, succeed in mastering the motor disturbances, especially when the patient becomes convinced that the exercises prescribed are within the boundaries of his strength and physical powers. One certainly must look to the action on the psychical element in pseudotabetics in order to find the explanation of the miraculous effects of the many new methods advertised by the daily press in a sensational fashion and utilized by some people for the shameless exploitation of public credulity. There is no need to describe all these methods; it is quite sufficient to glance through the lay papers in order to find instances. However, the fact must be pointed out with emphasis that the great majority of tabetics proclaimed to be definitely cured are only doubtful cases or simply pseudotabetics.

1. Pseudotabes is not as rare as has been assumed. It may be due to a number of different causes, such as intoxication, infection and overwork.
2. Pseudotabes may also have a syphilitic origin.
3. The symptoms recall those of true tabes dorsalis. They are distinguished by the intensity of their manifestations and by their complete disappearance ultimately.
4. It is characteristic of pseudotabetics to be cured completely in all instances.
5. Pseudotabes is distinguished from tabes dorsalis by the evolution of the symptoms, by their rapid development, and by their customary curability.
6. The treatment of election of pseudotabes must comprise treatment of the etiological cause and also symptomatic treatment. Physiotherapeutic treatment occupies a predominant place in the second instance. Thanks to the four physical agents, of which it is built up, this treatment renders great service in the therapeutics of pseudotabes, whatever the origin of the disease. Among these four physical agents, reeducation must be considered the most rational measure, being calculated to combat at the same time both the motor disturbances of progression and the psychic state of pseudotabetics.

Protein Sensitization with Special Reference to Bronchial Asthma, Hay Fever, and Eczema*

By MAXIMILIAN A. RAMIREZ, M. D.,
New York.

The theory of protein sensitization is so familiar and so much has been written on the subject that I shall not review the literature and present a discursive paper on its etiology; I shall only touch on those aspects which concern us as practical physicians and clinicians. It is impossible to say anything about it without quoting freely from I. Chandler Walker's classical researches. I wish to acknowledge a great indebtedness to him. His excellent writings have been of the greatest assistance to me in this work, and I take this opportunity to acknowledge my appreciation of the courtesy shown me while visiting his clinic.

Now, in what way are we interested in a subject which up to the past few years has been the concern only of research workers and professors of medical science? In what way does it enter intimately enough into our diverse practices to make worth while a discussion of this kind? Before answering these questions let us define protein sensitization. It is that state in which an individual is sensitive or hypersusceptible to some foreign protein to which he maintains a certain intrinsic physiological antipathy. This antipathy lies essentially in the blood, a product of the intricate chemistry of that tissue, about which we as yet know so little. By means of the blood it is disseminated throughout the entire organism, with the result that whenever there is absorption of the specific protein to which the blood is antagonistic, an unmistakable and typical reaction is set up, whether that absorption be by way of an abraded surface, as scarified epithelium, or by intact but vulnerable epithelium, as the conjunctiva or alimentary tract. How and why it is set up we do not know; it is an individual idiosyncrasy; and this remains a fascinating problem for some future Pasteur to solve. But we do know this—and this enters intimately into our practice—that even as individuals differ in susceptibility to the various foreign proteins, so do they differ in the type of their reaction. In one, the reaction may occur as the violent coryza so familiar to us as hay fever and rose fever, or what could be termed anaphylactic vasomotor rhinitis; it may occur as an eczematoid eruption; it may present itself as a gastric disturbance, or in a still more interesting fashion, as bronchial asthma.

The proteins may enter the body by inhalation, ingestion, absorption, and infection; by inhalation through the respiratory tract; by ingestion through the digestive tract; by absorption, apart from inhalation and ingestion, through the conjunctiva and to a less extent, the skin; by infection through the presence of pathogenic bacteria in any part of the body, especially in the teeth, tonsils, nose, throat, lungs, and intestinal tract.

Now let us consider the most common of these

proteins. Food proteins generally cause skin diseases, especially in children, as egg white, wheat, milk, beef, strawberry, oats, tomato, fish, almond, pork, buckwheat, oyster. The most common proteins causing hay fever are ragweed, goldenrod, red top, golden glow, sunflower, timothy, and corn. Emanation of hair of the horse and horse dandruff are the most common epidermal cause of bronchial asthma. Wheat and egg are the most common of the food proteins to cause asthma; oats, corn, beef, fish, almond, chicken, walnut, rye, pea, and peanut, the next active of the food proteins. Ragweed is the pollen protein most frequently causing asthma. In some cases these pollens caused hay fever, rather than asthma, and in other cases the pollens were probably the primary cause of the asthma but bacteria continued the condition.

The most frequent bacterial cause of bronchial asthma is the protein of *Staphylococcus pyogenes aureus*, the *Streptococcus hemolyticus*, the *Staphylococcus pyogenes albus*, and the *Micrococcus catarrhalis*. A patient may be sensitive to one protein or to a combination of proteins. He may react to several of the food proteins or to a combination of food, animal, plant or bacterial proteins. This is known as multiple sensitization. It is commonly found and is more difficult to treat than the cases of simple sensitization.

In the study of each case a detailed history of the patient is of the greatest importance. A note should be made of the age of the patient, home and business environment, occupation, habits, and family history, mode and season of onset, and the course of the disease during the beginning. The family history in asthma, hay fever, or food allergy is very important. It has been shown that patients with idiosyncrasies to some foreign protein apparently inherit the tendency in at least fifty-five per cent. of the cases; where the symptoms are due to bacteria the patients inherit the tendency in about ten per cent. If it is suspected that some foreign protein substance is the basis of the condition, the diagnosis consists of the identification of the protein. The particular food thought to be causing the symptoms should not be avoided before the test is made; the result may be a negative test which would not prove the sensitization. We know that patients who are susceptible to certain foods, animal dusts, and pollens, will react positively when a solution of the protein is applied to a scratch on the arm, called the skin or cutaneous test, or a solution of the protein in high dilution and in definite quantity is injected between the layers of the skin, which is the intradermal or subcutaneous test. Both of these are commonly used and the result is usually the same.

The intradermal test is more delicate than the cutaneous test, but has a more limited application. The objections to the intradermal method are: 1. It

*Read before the City Hospital Alumni Association, New York, December 15, 1920.

is more difficult to perform. 2. It is often quite painful and one can test only comparatively few proteins at each session. 3. There is greater danger of infection; it requires careful technic and the careful sterilization of all instruments and solutions used. 4. There is danger of causing serious reaction by the introduction of an overdose in a highly sensitive patient. 5. Frequent occurrences of pseudo-reactions.

For these reasons I have employed the cutaneous or skin scarification method almost exclusively, and it has been shown, not alone by my own work, but by careful and extensive studies carried on by Walker, to be just as accurate as the intradermal method with the added advantage of greater simplicity and less disturbance to the patient. The test is done as follows: A number of small cuts, each about an eighth of an inch long, are made on the flexor surface of the forearm. These cuts are made with a sharp scalpel, but are not deep enough to draw blood, although they do penetrate the skin. On each cut is placed a protein and to it is added a drop of tenth normal sodium hydroxide solution to dissolve the protein and to permit of its rapid absorption. At the end of half an hour the proteins are washed off and the reactions are noted, always comparing the inoculated cuts with normal controls on which no protein was placed. A positive reaction consists of a white elevation or urticarial wheal at the site of inoculation. The smallest reaction that we call positive must measure 0.5 cm. in diameter. All larger reactions are noted by a series of plus marks and any smaller reaction is called doubtful. If a smaller wheal surrounded by an area of erythema appears around one or two of the tests I consider it of great importance and insist on repeating the tests with these proteins at a later date. At times no wheal appears but a definite erythema occurs around one or two of the tests, and although this cannot be called a positive reaction it must be viewed with suspicion and the tests repeated.

In performing and interpreting the skin test there are a few things that should be remembered. Occasionally we get a negative reaction to a protein to which the patient is really sensitive if the test is performed immediately following an attack due to that particular protein. Occasionally reactions are obtained to food proteins of which food the patient has never eaten. This is due to an inherited sensitivity and, of course, these foods must be avoided. This is of importance in cases of wheat sensitization, where one would test against rye and corn to determine if these are safe for the patient to take instead of wheat. Occasionally a reaction is obtained, let us say, to corn, and the patient will say that he has never taken corn. This is explained, as mentioned above, as an inherited sensitivity.

Delayed reactions may also occur. A test which appears negative or doubtful when read a half hour after applying the protein, may become definitely positive twenty-four hours later. This is the exception, not the rule. A marked difficulty arises in the interpretation of cases which have been negative to all tests, but in which a clearcut anaphylactic asthma appears. In these cases there are three possibilities which must be considered and ruled out

before definitely labelling a case negative: 1. The great possibility of having omitted the causative protein from your test. 2. The possibility of a toxin and not a true protein being the cause. 3. The possibility that the patient may at the time of the test be in a stage of recovery from an attack and therefore, with the system loaded with free antibodies, gives a negative reaction to the test. Occasionally a patient gives a positive reaction with a protein that apparently has no bearing on his condition. In cases of this kind the patient may eat sparingly of that particular protein without symptoms arising, but if much of the protein is taken symptoms do arise.

We may differentiate between true or typical bronchial asthma and the atypical or asthmatic bronchitis by means of the cutaneous test. In the typical variety the patient will react positively to the protein or group of proteins which is responsible for the asthma, while the atypical case will give a straight negative to all tests. Occasionally one will find a patient who shows a wheal and erythema around every protein tried out, but it will be found that the control will also be positive, showing that there is at the time of test an abnormal irritability of the skin. These so-called dermatographic skins cause great difficulty; all tests must be discontinued and postponed to a future time.

Specific protein treatment, which is the most successful procedure, consists of treating or desensitizing the patient with those proteins to which the individual is found to be sensitive by the skin test. Bronchial asthma caused by animal emanation is successfully treated by subcutaneous inoculations of the offending protein. Before this can be done, however, skin tests must be made with varying dilutions of the particular protein in order to find out the initial therapeutic dose. Each week the dose is gradually increased. As the amount of treatment increases, the positiveness of the skin test progressively diminishes until the skin test becomes negative with concentrated protein and the patient becomes absolutely desensitized. The treatment outlined above is given in horse, cat, and dog cases, but in those patients who are sensitive to feathers, wool, and the hair or fur of other animals, it is easier to avoid these substances than to treat the patients with their protein. Pollen asthmatics are tested and treated in like manner with subcutaneous inoculations, and the treatment should be given preceding the pollen season, rather than during it. Patients who are sensitive to bacterial proteins are given subcutaneous inoculations with vaccines of that particular organism. Subcutaneous inoculations with offending food proteins do desensitize but the process is long and tedious. The method of feeding proteins has proved unsatisfactory in many cases. The most obvious treatment is to take the offending foods out of the diet and resort only to active immunization in epidermals, bacteria or pollen cases. In most cases this is a simple matter, with the exception of those sensitive to wheat, egg, and milk. The difference in the length of time required to desensitize the patient depends upon the size of the initial amount which the patient can take without symptoms. Climate does not benefit those

sensitive to proteins, with the exception of pollen cases and then only when the patient goes to a place where the particular pollen is not present. The bacterial cases are benefited by warm, dry climates.

In the bacterial cases and those with severe secondary bronchitis, intratracheal injections of oily solutions sometimes give marked temporary relief. For immediate relief of symptoms in paroxysms of true asthma, adrenalin is the drug *par excellence*, but a certain amount of caution must be observed, for some people are quite sensitive to its action and occasionally go into a state of collapse after its use. This reaction is especially likely to occur in asthma and allied conditions where the sympathetic nervous system is in a highly unbalanced state.

In the preparation of an autogenous vaccine for the treatment of the bacterial type of asthma or the relief of the secondary bronchitis, a sterile specimen of sputum is examined for the predominating organism, and if this corresponds with the reaction obtained by the skin test, a simple vaccine is used. If, however, the predominating organism is one other than that giving a positive skin test a mixed vaccine should be used, using the predominating organism and the one giving the skin test.

There is a group of cases of asthma, perhaps more correctly classified under asthmatic bronchitis, where we obtain no reaction to proteins—all the tests are negative. These cases are probably of infectious origin and are very refractory to treatment. I have a series of fifteen of these cases in which I have used injections of a nonspecific protein, using intravenously a secondary proteose as my antigen. In four of these cases I obtained relief of symptoms, in three marked relief, in two slight relief, and in the remaining six no improvement. This form of treatment, which has been extensively used in the treatment of chronic arthritis, is still in its infancy in asthma and allied conditions. In two cases of hay fever during the acute stage, I have injected the patients with secondary proteose without apparent influence on the symptoms or course of the disease. The question of passive anaphylaxis is one which must not be entirely overlooked, the clinical importance of which I called attention to, in a case which I reported (1). Whether this was a true case of passive anaphylaxis in the strict sense of the term, I am not prepared to say, for more careful laboratory study than was carried out in this case would be necessary before definitely determining this question.

The bronchial asthma cases may be classified as follows: Those sensitive to proteins and those not sensitive to protein. Then divide these into those occurring throughout the year and the seasonal cases. The cases not sensitive to protein are classified as due to bacteria, while those sensitive to protein are subdivided into those occurring throughout the year due to animals, food, and bacteria, and the seasonal cases due to pollens.

The prognosis of asthma with proper treatment is excellent in the sensitive cases, provided the patient has not chronic bronchitis or marked emphysema. The severity of bronchitis, the degree of emphysema, and the resistance of the individual to bacteria modify the prognosis in the nonsensitive type.

HAY FEVER.

In testing hay fever cases it is necessary to emphasize the importance of testing not only with the various pollens as is ordinarily done, but also with all the foods, epidermals and bacteria, for although most cases of so-called hay fever, or seasonal vasomotor rhinitis, are true pollinoses, a certain number are due to one of the other proteins, either entirely or as an associated sensitization, which aggravates the symptoms and the elimination of which is necessary in order to obtain complete recovery.

A great many patients show multiple sensitization and I am convinced that in order to obtain really satisfactory results, one must actively immunize against every pollen giving a definite reaction. This conclusion I believe is contrary to the view expressed by Walker, who asserts that immunization against the pollens giving the largest reaction of a botanical group is sufficient. For example:

If a patient reacts very strongly to ragweed and weakly to goldenrod, Walker advises using ragweed solely in the treatment. I hope I am not misquoting him but that is my understanding of his views on the subject. I feel justified in stating, after careful observation of several classical cases, that all the pollens giving a definite reaction should be used in the treatment. I have not collected my results, in a large number of cases that I treated this past year, but I know they have been much more satisfactory than in previous years and I expect them to be even more so next year, for I am starting the injections at least four months before the expected onset of the attack. I think this is important. Treatment should be started about four months before the pollen season and continued right up to it and at times during the season, dropping down to a small dose of a high dilution. I also believe it is necessary to carry the immunization down to a one in one hundred dilution, giving as much as ten minims of this dilution. The separate pollens in varying dilutions should be used and the dose adapted to the individual patient.

ECZEMA.

Our present knowledge of the etiology and specific treatment of eczema is so vague that any procedure indicating a clearer understanding of this condition is indeed worthy of special note. Only a small percentage of all eczema cases are anaphylactic, but it is essential that patients be thoroughly tested in order that they may be properly classified and treated.

Before concluding I will give a brief review of several cases exemplifying the various clinical types of protein sensitization.

CASE REPORTS.

CASE I.—C. H., male, aged fourteen, had attack of asthma on and off for the past four years. Between attacks he felt perfectly well. His previous history was negative and his family history was also negative. Skin tests with the various proteins showed a two plus reaction to herring. Elimination of this food from the diet resulted in a complete recovery. The patient was seen six months later and was absolutely free of all symptoms.

CASE II.—I. P., female, aged eight, had suffered repeated attacks of bronchial asthma for the past two years. Her tonsils were removed four years ago; no other previous illness. Family history was negative. Skin tests showed a positive reaction to wheat, rice and codfish. Complete elimination of these foods resulted in recovery. Patient occasionally suffered mild attacks, characterized by cough, wheezing and slight difficulty in breathing, but they were of short duration and caused her little discomfort. They are probably due to the taking of wheat inadvertently.

CASE III.—M. S., female, aged forty-five. She had had frequent and repeated attacks of asthma for the past eight years, but felt comparatively well between attacks. Skin test showed a four plus reaction to horse dandruff, and reacted to as high as one in 100,000 dilution. This patient was inoculated with increasing doses of horse dandruff. Symptoms gradually disappeared and she became absolutely free of all asthmatic symptoms. Close contact with horses now cause no discomfort.

CASE IV.—M. B., female, aged forty-seven. She had had asthma for the past fifteen years; had not had a good night's sleep in eight to ten years, and slept on a chair every night. For the past few years she had had a distressing cough, with expectoration, and shortness of breath; previous to this she was free from symptoms during the day, the attacks coming on at night. Examination showed a two plus reaction to goose feathers, a one plus to *Staphylococcus albus* and one plus to *Micrococcus catarrhalis*. Examination of the sputum showed the predominating organism to be a *Micrococcus catarrhalis*; there were some staphylococci present.

A mixed vaccine was prepared and injected weekly. The feather pillow was discarded and a hair pillow used in its place. Symptoms improved considerably on discarding the feather pillow. The cough and expectoration improved rapidly under the vaccine treatment, but some cough and slight shortness of breath still remained, due to emphysema and fibrous changes in the lungs. However, the patient now sleeps in bed every night and is comfortable.

CASE V.—J. W., male, aged twenty-two. He had had asthma for the past six years and had noticed the relation of dogs to his symptoms. Skin test showed a three plus reaction to dog hair. Patient was inoculated with varying dilutions of dog hair and can now come in close contact with dogs without discomfort.

CASE VI.—C. E., male, aged fifty-three. He had had repeated attacks for the past fourteen years; symptoms had been growing worse and finally there was constant cough with expectoration. He had had a dog in the house for the past seven years, but it was only within the past few months that he noticed any decided influence on his breathing when in close contact with the dog. Cutaneous tests were strongly positive to dog hair, goose feathers, beef, rice, oat, and rye; also to *Staphylococcus aureus* and *Micrococcus catarrhalis*. The foods to which he was sensitive were removed from his diet, and injections of dog hair and a vaccine of *Staphylococcus aureus* and *Micrococcus catarrhalis* given. The feather pillow was also discarded and a hair pillow

used instead. This patient improved rapidly and is now practically well, though he gets an occasional attack of embarrassment in breathing and cough, especially if exposed to dust or a cold wind.

CASE VII.—W. F. T., male, aged thirty-nine. Had suffered from asthma for the past two years, following severe bronchitis. Cutaneous tests were negative to the various foods, pollens, and epidermals, but positive to *Staphylococcus albus*, and *Streptococcus communis*. An autogenous vaccine was prepared and injected in increasing doses. The patient improved rapidly and two months later he was free from symptoms which have not recurred although treatment was discontinued nearly eight months ago.

CASE VIII.—C. G., female, aged twenty-five. Had suffered from asthma for the past five years; during the first three years only during August and September, but for past two years had had recurring paroxysms throughout the entire year. There were no hay fever symptoms at any time. Cutaneous protein tests were negative with the various foods and epidermals but strongly positive to ragweed and corn pollen and to *Staphylococcus aureus* and *albus*. A vaccine was prepared and injected during the winter, spring and summer months and injections of ragweed and corn started last May. The patient improved markedly on vaccine treatment and went through a season without symptoms.

I will not take up space by citing ordinary cases of hay fever, showing single or multiple pollen sensitization, but will review briefly the history of one or two hay fever cases showing sensitization to bacteria, foods, and epidermals, as this phase of sensitization as regards hay fever is often overlooked.

CASE IX.—C. J., female, aged twenty, for the past few years had had repeated severe attacks of sneezing, itching and running of the eyes, coming on especially during June, July, August and September, during which time she always went to her country home. She occasionally had similar attacks during the winter but they were not as persistent nor as frequent. Cutaneous tests were negative to the various pollens, foods, and bacteria, but strongly positive to the protein of horse dandruff. Repeated inoculations with this protein resulted in complete recovery and satisfactory protection.

CASE X.—H. H., female, aged thirty-five, had repeated attacks of itching and running of the eyes, coryza, and sneezing, coming on during June, July, and August. Cutaneous tests were negative with the various pollens, bacteria and epidermals, but strongly positive to strawberry, blackberry, and cantaloupe. The patient abstained completely from taking these fruits this season and was absolutely free from symptoms, except on one occasion, when she had a little itching of the eyes and sneezed once or twice after eating strawberry ice cream.

In conclusion, allow me to say that I do not intend to convey the impression that all patients with asthma and hay fever respond as satisfactorily to treatment as those which I have cited; for these are selected cases, reviewed for emphasis and exemplification. However, I do believe that a sufficient number are definitely of protein origin and can be materially helped, thus justifying the testing of all suspected cases.

Protein Desensitization From the Point of View of the General Practitioner

By J. FRANCIS WARD, M. D.,
Brooklyn, N. Y.

An increasing number of diseases are being recognized as of protein origin. Some of them have been very puzzling to the general practitioner and because the true character of the disease was not understood treatments have been hazardous and usually ineffectual. Among the disturbances which are frequently met with are various skin affections; infantile convulsions and epilepsy; digestive disturbances, such as auto-intoxication; indigestion and conditions simulating gastric ulcer; and hay fever and asthma. In fact it is not uncommon to have a patient present symptoms of more than one of these disturbances, which are eventually found to be referable to one or more proteins poisoning the system.

After a brief review of the subject of protein sensitization and my method of desensitization, the disturbances mentioned will be considered in the order named.

Brown (1) believes that the undue reactions caused by the protein of food may take place in

any tissue or organ of the body, and the symptoms produced do not depend upon the variety of the protein but upon the tissue in which the manifestation takes place. He, as well as O'Keefe (2), calls special attention to the evident hereditary tendency of protein sensitization, as it is not uncommon to find whole families sensitive to one or more protein foods. The source of the proteins is practically endless, including not only foods, but hair, dandruff, bacteria, and pollens from many trees and flowers. The method of determining to what protein or proteins the patient is sensitive is comparatively a simple matter. It has been fully described by Blackfan (3), Walker (4), Coke (5) and others.

Of the several tests to determine a patient's sensitization to proteins, the one which has proved safe and most reliable is the skin test, performed briefly as follows:

The flexor surface of the arm is thoroughly cleansed and a number of small cuts, not deep

enough to draw blood, are made, each about one eighth of an inch long. On each cut is placed a protein and to this is added a drop of decinormal (four tenths per cent.) sodium hydroxide solution. Proteins are permitted to remain on cuts for half an hour, after which they are washed off and the reactions noted, always comparing the inoculated cuts with normal control on which no protein was placed, but to which a drop of the solvent was applied. A positive reaction consists of a raised white elevation or urticarial wheal. Generally surrounded by erythematous blush, the smallest positive (one plus) reaction must measure 0.5 cm. in diameter. Any smaller reactions are doubtful. Negative skin tests with proteins rule out those proteins as a cause of the symptoms. All the proteins which react positively must be suspected. If the patient is sensitive to food proteins, such foods should be omitted from the diet for at least a month, following which it sometimes happens that the toxic food can be returned to the diet in gradually increasing amounts. Change in living habits usually is all that is necessary to avoid contact with toxic proteins whether foods or animal emanations.

In those cases where relief cannot be effected by change of daily routine, active treatment must be instituted. Reaction to pollens should be anticipated by pre-seasonal treatment. A course covering ten or twelve weeks and comprising at least twelve injections should be completed, if possible, before commencement of pollination. If, however, the pollinating season arrives before the completion of the necessary injections and continuation or repetition of the treatment is considered advisable, the initial dose must always be of such a high dilution that there is no skin reaction whatever and the increase of doses must be given more slowly than in the pre-seasonal treatment.

The majority of physicians treat cases of eczema by intestinal cleansing, such as calomel purges, intestinal antiseptics, and high enemas. Patients suffering from eczema are told by the dermatologist to eliminate red meats from the diet. Some of these patients are relieved, some cured, thus showing that they belong to the class which is sensitive to beef protein. Strawberries often cause urticarial rash almost immediately after ingestion. Sea food may act in the same way. It must be emphasized that no one food protein is at fault in all patients; it depends upon the particular protein to which the patient is sensitive.

According to the experience of Ramirez (6), in only a small percentage of eczema cases are the patients anaphylactic, but when the skin condition is associated with asthma or hay fever it is usually so. It is therefore essential that patients be thoroughly tested for protein sensitization in order that they may be properly classified and treated. O'Keefe (2) has reported observations upon seventy cases of dietary eczema in children under four years of age. The tests were made by linear scarifications upon the back instead of the arm, as is usually done in adults. Although the mother in no case showed sensitization to the protein to which her child reacted, nearly twenty per cent. gave a history of asthma, eczema, or urticaria in some other member

of the family. Elimination or modification of the offending food resulted in so markedly improving the children's condition that O'Keefe concludes that dietary regulation is essential in the treatment of eczema.

We know that attacks of infantile convulsions can be avoided or lessened by intestinal purging, enemas, and intestinal antiseptics. This directs attention at once to the food ingested. Formerly, teeth were considered as the inciting factor. Although some cases of epilepsy develop late in life, the great majority occur between the ages of two and seven. When we consider that this is the age when the child leaves his nursing mother to partake of adult diet, we witness an attack of convulsions which in a great many cases is a forerunner of a later epilepsy. In most cases of epilepsy there is no pathological lesion, excluding, of course, traumatism; the attack appears after a hearty meal. Such attacks are lessened or aborted by cleansing the intestinal tract thoroughly. In static seizures the accepted treatment is limited diet and intestinal cleansing by antiseptics and high colonic irrigations. Is it not reasonable to suppose that by this treatment we rid the body of all foodstuffs which contain the offending protein or proteins?

Dr. H. Geyelin, of New York, in a paper read before the American Medical Association in Boston, in June, 1921, told how very effective had been his fasting method of treating epilepsy. In the discussion following the paper, Dr. Stanley Cobb, of Boston, and Dr. Tom A. Williams, of Washington, spoke very favorably of Dr. Geyelin's theory. The method consists of putting the patients on a series of fasting periods. During these fasting periods they had no attacks, showing that the foods containing the protein to which the patients were sensitive were probably the cause of the epilepsy. Dr. Frederick De Lue, of Boston, also discussed the paper and spoke highly of advocating a diet. In view of this testimony and my own experience, I believe that food is the dominating cause of epilepsy. I think that if epileptics were tested and the foods containing the proteins which reacted positively were eliminated from the diet, we would see a great improvement in the patients, if not an actual cure of the disease.

I am inclined to believe that rheumatism and neuritis may also be caused in some cases by protein sensitization, just as in the case of skin disease and epilepsy. This field needs further investigation, however, before positive statements are warranted.

In certain digestive disturbances, however, sensitiveness to certain proteins has been definitely shown to be the underlying cause. Recently the French pediatricist, Grueit (7), reported on the toxic property of cow's milk made evident by the injurious effect on very young infants. The protein is not enzymatic in nature, and is apparently heat stable to a considerable extent. It is only imperfectly attacked by the digestive juices of the infant, and also is able to make its way through the gastroenteric wall and into the circulation, where it deranges the metabolism. Incidentally it often leads to nitrogen retention, and the symptoms of uremic intoxication become evident. The development of acidosis may

also be seen. In general, the condition invariably terminates in a wasting process.

Still more recently the experimental work on rats done by Hartwell (8) showed the extraordinary reaction which will follow upon the excessive ingestion of a specific protein. In this experiment caseinogen, added to the diet of the nursing mother, caused the death of the rats while the mother remained in apparently good health. The few rats which survived the lactation period were not successfully weaned. The young rats had fits, exhibited extensor and contractor spasms, and just before death extreme exhaustion was evident. While it is unlikely that a nursing woman would ever take so large a proportion of a specific protein as was given in these experiments, it is clear that excessive protein in the mother's dietary may lead to metabolic and nervous trouble in the nursing child.

Case I, reported at the end of this article, is typical of my experience with protein intoxication causing gastric symptoms. Ramirez (9) reports the case of a child of seven who had attacks of severe epigastric pain. The attacks came on three or four hours after eating and lasted thirty minutes. X ray examination showed a decided pylorospasm. The protein test showed a strongly positive reaction to whole egg. Four months after the entire elimination of egg from the diet the child had only occasional attacks, but the skin test was still slightly positive. Ramirez believes the occasional attacks were due to the presence of some egg in the food. He has had four cases of pylorospasm with moderate increase in gastric acidity of definite anaphylactic origin in which the spasm completely disappeared on removal of the offending protein.

That hay fever and asthma may be cured by protein desensitization is probably more generally recognized than the diseases previously referred to. Undoubtedly this is due to the fact that individuals affected with these respiratory diseases noticed the connection with flowers and attention was directed into the proper channel. Among those who have done excellent work in this field are Walker (4, 10), Babcock (11), Thro (12), Donnelly (13), Cooke (14), Ramirez (9), Coke (5) and Luckie (15). Naturally a diversity of methods has been the result of the various researches. Experience has shown, however, that essentially the treatment outlined at the beginning of this article has been most practical, as well as gratifying in results. Therefore no other methods will be detailed at this time and the reader is referred to the bibliography for the historical development of this treatment.

Ramirez (16) has reported a striking case illustrating an acquired anaphylaxis. A man was transfused with 600 c. c. of blood with no immediate discomfort. Two weeks later, on going out for a drive, he was seized with violent asthma. He had never had any symptoms before. It was found that the donor of the blood was an admitted horse asthmatic, and on testing it was found that he was sensitive to a much higher dilution than the recipient. Another man who had received blood from the same donor presented no symptoms of asthma.

The following case reports are typical of my observations with the effect of protein sensitization:

CASE I.—J. D., German, butcher, aged forty-two years. Chief complaint: stomach trouble for the past five years with symptoms typical of gastric ulcer. He had been to various stomach men who diagnosed his case as gastric ulcer of the pylorus and advised operation. As he refused this he was referred to me as possibly suffering from anaphylaxis. His radiograph was negative. Tested with the various proteins on his diet list, he showed four plus to beef, three plus to onion and two plus to cabbage. Without questioning the diagnosis of gastric ulcer, I told him to eliminate these three foods from his diet and report back to me after a week. At his second visit he informed me that he had suffered from none of the symptoms during the past week. I then had him try eating a little beef, onion and cabbage for a week. At the appointed time he reported that he had had a return of the symptoms. He then completely eliminated these three foods for a period of six weeks and reported that he had had no return of the symptoms. He has now gone for four months without a recurrence.

CASE II.—J. D., a boy of three years, had suffered from eczema for two years. He had been treated by various physicians without success and was referred to me for a protein sensitivity test. He showed three plus to white of egg and two plus to potato. His mother eliminated these two foods from his diet and by the end of a week the rash had entirely disappeared.

CASE III.—Mrs. R. S., aged forty-nine years. Chief complaint: slight attacks of hay fever and eczema starting about the middle of August and continuing to the latter part of September, every year for the past ten years. She was sent to me in June, 1920, to be tested for the possible cause of the hay fever. She showed five plus to ragweed and two plus to daisy. I started treatment at once to immunize her and she passed through the fall season with no attack of hay fever and no sign of eczema. I believe the eczema was due to the ragweed.

CASE IV.—R. H., a boy of nine years. Chief complaint: asthma for six years. He was referred to me for protein diagnostic tests. He was found to respond four plus to chicken feathers. He lived on a farm where there were a number of chickens and he slept on a feather bed and mattress. A hair mattress and pillow were substituted with some relief. This was in January of the present year. I was about to start immunizing him against chicken feather protein when his aunt informed me that she dreaded the spring and fall because they seemed to aggravate his symptoms. I then tested him for the spring and fall pollens. He showed six plus to orchard grass and five plus to ragweed. I started treatments with orchard grass. I did not use feathers as he could partially avoid them. The twelve treatments for orchard grass were finished by the middle of June. During this period he had had but two attacks which were very slight. From the middle of June alternate treatments for immunization against ragweed and feathers were given.

CASE V.—N. S., a man of twenty-eight years, a chauffeur, had suffered from asthma for twenty years. His mother told me that as a young boy he

was in the habit of playing in a stable near their home. It was at that time that he first showed asthmatic symptoms and he was taken to a doctor. She supposed he had catarrhal bronchitis, but the doctor diagnosed a typical asthma. The boy had always lived near stables and he had noticed that he always had attacks when he came near horses. Of late years he had had symptoms when he drove the automobile into the country. Tests for horse dander and the spring pollens showed him to be four plus sensitive to the former and six plus to timothy grass. Alternate treatments for the two proteins have effected a partial immunization. He has had four slight attacks since last February. The treatments for horse dander have not yet been completed.

CASE VI.—Mrs. F., aged thirty-five years, a sufferer from asthma since she was sixteen years of age. Tests for all proteins were negative except for *Staphylococcus pyogenes aureus*. Twenty-two treatments brought about no immunization.¹

Pollen Protein Intoxication in Nonseasonal Bronchial Asthma*

A Study of Thirty Cases

By ALEXANDER STERLING, M. D.,
Philadelphia.

During the past few years much has been written about food protein sensitiveness and animal emanation sensitiveness as exciting causes of asthma. In September, 1918, at a meeting of the Pennsylvania State Medical Society, we expressed our disappointment in food protein sensitiveness (1). If we stopped at food tests and did not look for other factors as a cause for the paroxysm, we should certainly be far from doing good to our patients, notwithstanding the fact that in some cases it might be the only cause producing the asthmatic paroxysm, as has been so ably presented by Dr. Walker, of Boston. We have thus made it our practice to have each patient tested for all food proteins, animal emanations, bacterial proteins, and all pollens routinely, in all one hundred or more tests.

Pollination has been considered by all asthma students as a cause of hay fever and seasonal asthma; in other words, pollination is understood to be the exciting factor responsible for the occurrence of hay fever in the spring, summer and fall, which in some cases is accompanied by asthmatic paroxysms during the pollination period. Testing the patients

routinely on a large scale, we find that the majority who suffer from asthma all the year round, or so-called nonseasonal asthma, show positive skin reactions to one or more pollens, and that in some of them it was never accompanied by any symptoms of hay fever, as far as the information from the patients was concerned. Eight patients, or about one third of those tested, showed positive skin reactions to pollens only. One patient, who was positive to ragweed pollen from ninety tests, had had asthmatic paroxysms throughout the year since childhood. Another patient was positive to corn pollen from eighty tests, who had had paroxysms throughout the year for ten years. Still another was positive to all pollens of the spring, summer and fall, and had had paroxysms throughout the year for fifteen years.

True, a certain number of this type of patients, who had had hay fever symptoms for a number of years previous to the development of asthma, for the last few years did not have any symptoms of hay fever, but had had asthma throughout the year; thus, pollination, which is probably the exciting factor responsible for the paroxysms, was not thought of by the patient or the physician. My observa-

*Read before the Philadelphia County Medical Society, June 8, 1921.

tion of the thirty cases lead me to believe that in sixty-six per cent. of the patients suffering throughout the year the asthmatic paroxysms are due to pollination; hence, nonseasonal asthma is not necessarily due to bacterial infection only, unless pollen sensitiveness is also excluded from the diagnosis. Some of these patients had positive skin reactions to both fall and spring pollen, while others had positive reactions to either fall or spring pollen.

The asthmatic paroxysms were evidently due to the pollen in question, as an exciting factor, because the patients improved when desensitized by the offending pollen or pollens, and sixty per cent. of them had no more paroxysms after a few desensitizing doses. Some of these desensitized patients have remained well, while others have had a return of the asthmatic paroxysms occasionally. In the other forty per cent. desensitization did not make any improvement, possibly due to the presence of various complications, such as emphysema, myocarditis, irreparable nasal and throat abnormalities, and general endocrine disturbance in two female patients, possibly of ovarian origin. The frequency and severity of the paroxysms are the same as before, although in some of them no other positive skin reactions could be demonstrated by rather extensive skin tests. One patient, A. P. G., after fifteen desensitizing injections showed no improvement in the asthmatic paroxysms, and on retesting gave the same positive reaction as when treatment began.¹

We think that, fundamentally, patients sensitive to a certain pollen cannot throw off the pollen protein intoxication when once they have come in contact with it, and that state is kept up by some patients throughout the year, and in others irregularly throughout the year. In the same manner one of the patients who had so-called horse asthma, giving a positive skin reaction four plus to horse dander and horse serum, suffered from paroxysms all the time, whether he was near horses or not. Of course this patient stated that he would be worse or his attacks more violent when he happened to be near horses, but the asthmatic paroxysms were always present, though he might be miles away from horses. A similar history is obtained from the pollen asthmatic; that, though he might have paroxysms throughout the year, he might be decidedly worse at the pollination period.

The majority of asthmatics were found sensitive to some form of food protein, animal emanation, and pollen proteins—twenty-four out of thirty; a lesser number, or twenty per cent., did not show any sensitiveness by the skin reaction tests to the above mentioned proteins, hence, we should be guarded in stating that proteins were the only exciting factors responsible for the production of paroxysmal dyspnea. Many doctors are of the opinion that in all those patients who do not show sensitive skin reactions to food or animal emanation the asthmatic paroxysms are bacterial in origin and that good results are obtained from autogenous vaccine. In a great many of my own patients, the results from autogenous vaccine were far from favorable, al-

though the vaccines were prepared in a good laboratory, according to the method as suggested by its advocates.

Desensitizing a great number of patients and carefully recording the results, testing and retesting them every two months in the course of their treatment, we are impressed by the following conclusions: That a pollen positive asthmatic should be desensitized for the particular pollen or pollens he shows a positive reaction for, no more and no less. This rule applies also to seasonal rhinitis, or so-called hay fever. To be more specific, the majority of the pollens are classified as Graminæ, Compositæ, Leguminosæ, and so on.

If a patient is positive to ragweed, goldenrod, golden glow, and daisy, you cannot desensitize him so as to improve the asthma by injections of ragweed alone, although they all belong to the same class, Compositæ. It will be necessary to inject an extract containing all of the above mentioned pollens to which the patient has shown a positive reaction, in order to get well. Again, if a patient has had a positive reaction to timothy and red top, you will not have satisfactory results when using a polyvalent pollen containing timothy, red top, June grass, orchard grass and rye, although they all belong to the same class, Graminæ. If you do, you will induce an acquired sensitiveness in the patient for the other three pollens, which he was not sensitive to originally, for this has repeatedly and distinctly shown to be the case by retesting these patients in the course of the desensitization treatment.

The same reaction happened in the case of horse dander and horse serum positive asthmatic, mentioned above. After three months of horse dander desensitization, the patient's improvement was not marked, but on the addition of horse serum desensitization, the patient made a marvelous improvement and at present is free from asthma. Therefore, desensitization should be more specific in order to get proper results, with fewer failures. A specific pollen extract prepared according to the positive reaction tests obtained from the patient could be made to order in from four to six days, by simply making the proper dilution from concentrated stock extracts.

In conclusion, I would like to state that those of us who are engaged in studying and treating paroxysmal dyspnea, or so-called asthma, realize that much is yet to be learned before the problems of the asthmatics are entirely solved. I am presenting to you the results of my observations as I find them, without any exaggeration on my part and carefully guarding against undue enthusiasm in the application of the protein work, and ask that you consider and discuss them. To treat paroxysmal dyspnea successfully, we must intelligently apply our knowledge of general medicine and therapeutics, to test the patients routinely, so as to exclude any sensitiveness or anaphylactic factors of any nature, or to treat them, which depends upon the accuracy with which the cutaneous sensitization tests are performed and interpreted. It depends upon the accuracy and specificity of the methods of desensitization, which should be checked up by repeating tests at intervals to determine the progress of the

¹ This patient called at the office, since this paper was written, and stated that he felt greatly improved.

case in relation to desensitization. Last, but not of least importance, it is necessary to correct any nose and throat abnormality, as well as to treat any possible or probable focus of infection.

SUMMARY.

In this series of thirty cases, twenty patients, or sixty-six per cent., had positive skin reactions to one or more pollens, which apparently had been the exciting factors in the production of the paroxysmal dyspnea throughout the year.

EIGHT CASES OF POLLEN SENSITIVENESS ONLY.

1. J. B. R. Corn, three plus.
2. E. R. W. Corn, three plus; ragweed, short, three plus; sunflower, one plus; goldenrod, one plus.
3. I. R. Corn, one plus; ragweed, short, four plus; ragweed, giant, one plus.
4. A. P. G. Ragweed, short, two plus; ragweed, giant, one plus.
5. C. B. Ragweed, short, two plus.
6. H. S. Corn, one plus.
7. J. S. Ragweed, short, two plus; ragweed, giant, one plus; goldenrod, one plus; daisy, one plus; red top, one plus; golden glow, two plus, dahlia, one plus.
8. H. R. Corn, two plus.

TWELVE CASES OF MIXED SENSITIVENESS, IN THE MAJORITY POLLEN SENSITIVENESS PREDOMINATING.

1. A. S. B. Ragweed, short, four plus; ragweed, giant, four plus; timothy, four plus; red top, four plus; orchard grass, four plus; June grass, four plus; corn, four plus; goldenrod, four plus; daisy, four plus; dock, poplar, maple, tomato, goose feathers, cucumbers, wheat, and potato, each had one plus.
2. M. D. Mc. Ragweed, short, three plus; ragweed, giant, two plus; corn, two plus; June grass, timothy, dog hair, and pneumococcus, each one plus.
3. I. E. Corn, four plus; goldenrod, two plus; ragweed, short, one plus; rye protein, two plus.
4. William W. Corn, one plus; chicken feathers, two plus; Staphylococcus pyogenes aureus, one plus; Streptococcus, nonhemolyticus, one plus.
5. B. Th. Ragweed, short, one plus; goldenrod, one plus; sweet vernal grass, one plus; rye pollen, one plus; egg white, two plus; egg yolk, one plus; cheese, one plus.
6. J. H. Corn, one plus; tomato, one plus.
7. Th. S. Corn, two plus; ragweed, short, one plus; tomato, one plus.
8. C. N. Ragweed, short, one plus; corn, two plus; timothy, one plus; chicken feathers, two plus; potato, two plus.
9. S. E. Ragweed, short, one plus; corn, one plus; locust, two plus; willow, one plus; rabbit hair, three plus.
10. B. S. Ragweed, short, two plus; ragweed, giant, one plus; corn, two plus; carrot, one plus; sheep's wool, one plus.
11. H. S. Ragweed, short, three plus; goldenrod, one plus; corn, one plus; rice, one plus; onion, one plus.
12. M. W. Rabbit hair, three plus; clover, one plus.

TEN CASES NOT SENSITIVE TO POLLEN.

Of the ten cases not sensitive to pollen, three were sensitive as follows:

1. M. R. Horse dander, four plus; horse serum, four plus; almond, two plus; hickory nuts, one plus.
2. Mrs. J. C. A. Cabbage, one plus; lima bean, one plus; oysters, one plus; rye, one plus; butternut, one plus; black walnut, one plus; peanut, one plus.
3. Mg. W. Sweet potato, one plus; Streptococcus hemolyticus, one plus.

SEVEN CASES HAVE NOT REACTED TO EXTENSIVE PROTEIN SKIN TESTS.

1. Mrs. Vi. Myocarditis.
2. C. L. Loss of pulmonary elasticity—apparently no chest expansion.
3. DeL. Atrophic pharyngitis.
4. Dom. Gases from the acids and dyes in the leather industry.

5. Sol. Myocarditis and arteriosclerosis.
6. Na. Apparently no pathological condition.
7. Dub. Mitral regurgitation, right basal pleurisy, cystitis.

CASE HISTORIES.

The majority of histories obtained from asthmatics may not be of great value, but now and then one sees patients whose histories are of rather more than passing importance and I should like to present the histories of several cases which I consider of interest:

CASE I.—Mrs. I. R., a native of Philadelphia, thirty-nine years old, married five years, no children, no miscarriages. Menstruation was normal, of the twenty-eight day type. She had had measles three times, left sided pleurisy eleven years previously for ten days. Her mother died at the age of fifty-five—cause unknown; father living and well. One brother had had asthma and hay fever in the fall for a number of years. Four of an aunt's children (on the father's side) had died from tuberculosis of the lungs. Her father's sister had died of tuberculosis of the larynx and her mother's brother had died of tuberculosis of the lungs. Patient was well built; height five feet five inches, weight 185 pounds.

The patient had had hay fever for nine years from August 15th to frost and never before had been accompanied by attacks of asthma. In May, 1920, three teeth were extracted under nitrous oxygen anesthesia, shortly after which attacks of asthma developed and no attacks of hay fever occurred the following fall. She had had good medical attention with no relief, followed by three or four months of osteopathic treatment, with no improvement. On the advice of a colored woman she was taking kerosene oil, twenty to fifty drops, two to three times a day. She had been free from asthma for forty days, but had had to discontinue the oil on account of a furunculosis produced by it.

At my first call, her temperature was 101° F., and during the following four or five months the temperature was normal most of the time, but occasionally she would have a fever for a number of days, but for two months it was normal. The pulse was always between 120 to 130. Dyspnea was very marked, chest was full of musical sounds, and there were moist râles at the base of both lungs. Marked greenish yellow expectoration. Coughing was about the same day or night. She slept at intervals in a chair, fearing the bed on account of a choking sensation. She had coughing spells, lasting from ten minutes to two hours, terminating in a desire to vomit, but she did not vomit, except occasionally in the morning. She always felt cold, had crying spells, suffered from hoarseness occasionally. Urine, on several examinations, was negative; sputum, three examinations, negative to tubercle bacillus. A culture from the nose and throat, and sputum was full of pneumococcus, staphylococcus, pyogenes aureus, the streptococcus hemolyticus and the influenza bacillus. Blood pressure was 180 to 160 systolic, and from 120 to 100 diastolic. There were no abnormalities in the nose and throat and no cardiac murmurs. The patient had ninety skin tests with the following results: Ragweed short plus four, ragweed giant plus four, timothy plus three, corn

plus one, and daisy plus one; doubtful to sunflower, goldenrod and to the proteins of wheat, potato and rye. I should like to remark, at this point, that this patient, though being strongly positive to timothy pollen, which is considered a spring pollen, had never had spring rhinitis, or so-called rose fever.

The patient was given desensitizing injections and after the first week was free from asthma and kept well for two months. On retesting, she was found to be still positive to the two ragweeds. Desensitization was continued for two more months and when retested the third time she was found to have no more positive reactions.

Suspecting some endocrine disturbance, ovarian extract and corpus luteum, of each five grains, were given in a capsule with good results. She still had an occasional attack of asthma once a week or once every two weeks. Her pulse varied from 120 to 130, and no medication would bring the rate down. She refused to stay in bed. I consulted a cardiac specialist and his opinion was that the high pulse and high blood pressure might possibly be due to the oncoming menopause. On March 1, 1921, the patient had a severe attack of angina and was put to bed for three weeks. Her pulse went down to 68 and is now about 90, for the first time in six months.

Summary.—Pollen intoxication, glandular disturbance, possibly of ovarian origin; a possibility of tuberculosis, although no tuberculosis was demonstrated by the x ray and the sputum was negative repeatedly.

CASE II.¹—Mrs. M. W., of Philipsburg, N. J., thirty-six years old, married six years; two children, five and two years respectively; had had no miscarriages; menstruation normal. She had had measles in childhood and pneumonia eight years ago. Grandmother on her father's side had asthma at forty years for a number of years.

The patient had had asthma for fifteen years, all the year round, but for the last four years she had been free from May to September, but from September to May the asthma had been very bad. The attacks were irregular throughout the year and were getting worse with each childbirth. It started during a cold summer when she contracted a cold. The paroxysms were the same day or night, with a yellow, frothy expectoration. Attacks were preceded by rhinitis and sneezing, with dyspnea on the slightest exertion, marked cyanosis, and cold perspiration. The patient's appetite was good. There was a great deal of belching and constipation, with offensive stools. She had no knowledge of any animal or pollen sensitiveness. She had many times walked through fields without any bad effects, but thought that milk, onion and cabbage made attacks worse. She had taken large doses of morphine for some time, the only medicine, she said, which made her comfortable. No abnormalities in the nose and throat could be detected. Urine, several examinations, was found negative, and sputum, after several examinations negative to tuberculosis. Blood pressure was 100 systolic; 70 diastolic, with

some variation on different examinations. There was marked cardiac dilatation with feeble heart action and weak radial pulse. A mitral systolic murmur, of a blowing type, was not transmitted. From ninety skin diagnosis tests, she was found positive to streptococcus hemolyticus plus one, sweet potato plus one, and doubtful to the proteins of oyster and orange and to the pollens of red top and timothy.

The patient was referred to her family physician, F. A. Wolf, of Philipsburg, N. J., with the suggestion that she be put to bed for two months, to improve the heart muscle, and also to inject stock vaccine containing streptococcus hemolyticus for the purpose of giving the physician a chance to watch the patient, rather than expecting any curative effects from the stock vaccine. Digitalis, bromides and arsenic were prescribed with other minor suggestions. She improved wonderfully and in December, 1920, Dr. Wolf wrote me that she was doing well. She had not had an asthmatic attack during the past four weeks. He had examined her chest and found her lungs clear, no râles of any kind. The first heart sound was a little weak, but otherwise she was in good condition. At present she is walking around, attending to her home duties and is feeling quite well, except for an occasional precordial pain.

Summary.—This patient apparently was not sensitive to pollen. No abnormalities in the nose and throat could be detected, although rhinitis and sneezing always preceded her asthmatic attacks. The plausible diagnosis in this case is: Marked cardiac dilatation without hypertrophy, a mitral systolic murmur, possibly due to the cardiac dilatation, because it was not present three months later when she called for relief from the precordial pain that she experienced occasionally.

CASE III.—Miss C. B., a native of Philadelphia, aged eighteen years. She was employed in an office but had never worked a full week. Her family history was negative. She had had measles in childhood and asthma since infancy. She was treated for worms up to the age of twelve, when a physician informed the parents that she had asthma. She had always been weak, suffered from dyspnea on exertion, and had been troubled with rhinitis and attacks of sneezing, which were worse in the fall and throughout the entire winter, but were usually better in the spring. Last spring, however, the attacks were very bad. They came on at two or three o'clock in the morning, and were accompanied by dyspnea and choking but very little cough. The attacks also came on when she was excited or when laughing heartily. The patient was well built, five feet five inches in height, and weighed one hundred and forty-five pounds. Menstruation was normal; urine negative; sputum negative; blood pressure 120 systolic, 85 diastolic. She had a deviated septum with spurs and was sent to a rhinologist for a submucous resection, but there was no improvement in the paroxysms. From one hundred skin tests she had a positive reaction to ragweed (short) three plus, and goldenrod one plus. Desensitization was made with a stock extract containing ragweed, goldenrod and corn. The patient improved wonderfully and for the next six months, for the first time in her life, she worked every day. On retesting, she was

¹ This patient called to the office since reading this paper. There was a return of the asthmatic prooxysms, in a much milder form, possibly due to a pregnancy of four months.

found to be negative to ragweed and goldenrod, but positive to corn one plus, to which she was not positive originally. I mention this fact because it is contrary to the impression that polyvalent pollen extracts may be used with impunity. This patient is still having attacks once in three or four weeks, though they are mild and are probably due to the acquired sensitiveness to corn extract which she showed on further retestings.

CASE IV.—Mrs. H. C., a native of Philadelphia, aged forty-six years. She was married fifteen years ago, had had no children, and no miscarriages. The menopause occurred one year ago. She had had whooping cough twice, once at the age of five and again at twenty-five. She had also had influenza twice, in the last attack spitting up blood for one night, and had had pneumonia two years ago. Her father had had asthma for twenty-five years and died of Bright's disease at the age of fifty-five. The patient had had asthma for thirteen years, but never had had hay fever, rhinitis or sneezing. She was unable to walk more than a block at any one time on account of dyspnea on exertion. The attacks were worse at night around two o'clock in the morning, and last year she was worse in September. The patient said that she did not notice any sensitiveness to grasses or plants nor to any animal emanation, but she had observed that potatoes, milk dressings, rice pudding and vegetable soups made her attacks worse. She had suffered from disorders of the stomach for a number of years with belching, regurgitation of a good deal of sour mucus, bloating after meals, vomiting after breakfast, globus hystericus, and so on. She had had osteopathic treatment three times a week for six months.

The patient was well built; height five feet four inches; weight one hundred and fifty pounds; temperature 99.5 degrees; pulse 100; heart enlargement downward and to the left, no murmurs, cardiac sounds not distinct; no abnormalities in nose and throat; urine negative on several examinations; sputum negative to tubercle bacilli on two examinations; blood pressure systolic 125, diastolic 75, with slight variations under different occasions. We made about one hundred skin tests on the patient and found that she reacted to ragweed (short) three plus, goldenrod one plus, corn one plus and the proteins of onion, rice, beef and celery, each one plus.

Patient was given desensitization injections and at the time advised to abstain from the foods to which she had a positive reaction. After two weeks no paroxysms occurred and at present she experiences merely a slight dyspnea on exertion due to the presence of myocarditis, otherwise she is well. Practically all her stomach trouble improved when the proteins mentioned above were removed from her diet. When retested, after eighteen desensitizing injections, she did not react to the pollens to which she had originally been positive.

CASE VI.—Mr. G. A. R., a native of Pennsylvania, musician by profession. He had been married nine years, he had one child, and his wife was well. Family history was negative. The patient

had had influenza and pneumonia two years before and measles and whooping cough in childhood. He had suffered from asthma for the past twenty years, the attacks being worse at night. He felt badly in the winter but was worst in September. He was using a proprietary inhalation which gave him some relief but carrying the inhalation apparatus constantly with him was inconvenient. The asthma attacks were made worse by exertion, stooping down, and contact with horses. He was unable to assist his father in his shoe store as contact with the farmers would cause a severe attack of asthma. While a boy he was around horses a good deal but never noticed any ill effects until about twenty years ago. He had been getting worse since.

From one hundred tests the patient was positive to horse dander four plus; horse serum four plus; almonds two plus; hickory nuts one plus; doubtful to parsnip, buckwheat and peach. The patient was given desensitization injections of horse dander. Mild and severe reactions interfered with his regular attendance, but gradually increasing doses were kept up for five or six months with very little improvement. The patient was retested every two months and he gave about the same reactions to horse dander and horse serum as he had originally. He stated that he had never had antitoxin injections nor had he, to his knowledge, ever eaten horse meat, but the persistent reaction to horse serum could not be ignored, especially when he did not improve on horse dander desensitization although strong dilutions were used.

We obtained his consent to further injections of horse serum, starting with one twentieth of a drop, gradually increasing to one drop, then suddenly increasing from one to two drops. This was followed by a marked local reaction. The arm was swollen from the tip of the fingers to the shoulder, but there was no marked constitutional reaction. The swelling subsided in from seven to ten days. Exercising great care, but disregarding the swollen arm which invariably followed each injection, in the course of three months the dose was gradually increased to five drops which was injected subcutaneously in the inguinal region. The local reaction was very marked and the patient was unable to walk for a week or more. This patient presented apparently a case of true anaphylaxis where the interaction of anaphylactic antibodies and specific anaphylactogens produced an acute hyperemia of the skin where the injections were made. (Kolmer.)

To make a long story short, the patient had noticed a disappearance of the asthmatic paroxysms following horse serum desensitization. This was apparently a case of horse asthma in which the patient gave a reaction of four plus to horse dander and horse serum, did not improve on horse dander desensitization alone, but on the addition of horse serum the results were better. Hence, desensitization should be more specific.

The Endobronchial Treatment of Bronchial Asthma and Asthmatic Bronchitis

By MARK J. GOTTLIEB, M. D.,
New York.

The purpose of this paper is to report the appearance of the bronchi in cases of bronchial asthma and asthmatic bronchitis and the results of treatment by topical applications to the bronchi in such cases. Galebsky reports redness and swelling in one section of the bronchus. Horn reports a spasmodic stenosis simulating scar formation which on subsequent bronchoscopy was not found. Jackson observed in two cases during attacks of asthma that the mucous membrane of the bronchus was purple and not red, no stenosis being evident, and the bronchi were filled with secretions. Freudenthal reports the appearance of a scarlike mass closing the entire bronchus. This was overcome by applications of twenty per cent. cocaine solution.

In 1910 Ephraim reported one hundred and three cases of asthma treated endobronchially with a spray of suprarenin and novocaine. Ultimate results were known in eighty-eight cases. The result in seventy-three was reported as good, in forty-eight of which the patients were free from recurrence, some of them for a period of one and a half years. In seven cases the attacks were lighter and occurred with less frequency. Horn, in 1910, reported a case of asthma in which five bronchoscopies were performed, using each time a twenty per cent. solution of cocaine with a few drops of epinephrine. The result, as he reported it, was far from satisfactory. Freudenthal, in 1911, reported the results of the treatment in thirteen patients, eight of whom he considered cured, three improved, and two not benefited; but I believe that since then Freudenthal has revised his opinion regarding the number of cures, being less than he had first thought.

The foregoing workers dealt entirely with the endobronchial picture and the treatment of the condition in the bronchi and apparently did not make an effort to uncover the etiological factors concerned in the production of the symptom complex called asthma, except probably in so far as intranasal or throat disease was concerned.

All of the thirteen cases herein reported have been tested for skin sensitiveness with one hundred and nineteen proteins consisting of bacterial, epidermal, and food proteins. When indicated they were tested with pollens. Nose, throat, and teeth examinations were made and the pathological conditions found were eradicated wherever possible. Radiographs were taken of the lungs and when necessary of the paranasal sinuses. Complete bacteriology of the nasal secretion, tonsils, teeth, sputum, and stool was attempted and the patients tested for skin sensitiveness with suspensions of the various bacteria isolated. In the majority of these cases the urine was examined for possible evidence of nephritis and the blood for Wassermann reaction and uric acid content. A short résumé of each history giving the abnormal findings and treatment will be presented. In the cases where no skin sensitiveness was elicited

epidermal, food, or pollen proteins, although the patients were found sensitive to bacterial proteins or autogenous bacterial suspensions, they were considered as cases of asthmatic bronchitis, whereas those sensitive to epidermal, food or pollen proteins were considered to be cases of bronchial asthma.

ASTHMATIC BRONCHITIS.

CASE I.—Mr. J. R., fifty-six years of age; sick for thirteen years. He complained chiefly of dyspnea, cough, constant expectoration, and general weakness. Attacks were perennial. Radiograph of chest revealed the bronchial shadows to be very well defined throughout, especially at the bases. Sputum revealed the presence of *Streptococcus nonhemolyticus* and *Staphylococcus aureus*. Bronchoscopy showed the mucous membrane of both primary bronchi to be intensely red and swollen, with large quantities of thick mucopurulent sputum exuding from all secondary bronchi. He was treated with adrenalin one to one thousand solution, silver nitrate ten per cent. solution, a mixture of menthol and guaiacol two and five tenths per cent. each in sweet almond oil, 1.5 c. c. of which was deposited in both main bronchi. The condition was considered hopeless and no further treatment was given.

CASE II.—Mr. M. G., sixty-one years of age, sick seven years. He complained chiefly of dyspnea and expectoration, which were worse about seven o'clock in the morning when he arose. He was worse in the winter. He had pyorrhoea alveolaris and chronic ethmoiditis on the left side. Radiograph of the chest revealed the bronchial shadows to be intensified throughout the chest, especially at the bases. In addition there were several places in the right and left lung just external to the hilus which gave evidence of peribronchial fibrosis. Sputum revealed the presence of *Bacillus mucosus capsulatus* and *Bacillus influenzae*. From the teeth *Streptococcus hemolyticus* was isolated. A vaccine containing *Bacillus influenzae* and *Bacillus mucosus capsulatus* was given. Most of the injections were given subcutaneously and a few intravenously, twenty-four in all, without the slightest amelioration of his symptoms.

Bronchoscopy revealed the presence of large quantities of grumous, mucopurulent sputum issuing from all secondary bronchi. The patient was bronchoscoped three times at intervals of about one week each and at each time he was treated with ten per cent. solution of silver nitrate and five c. c. of orthoform and tannic acid mixture was deposited in each main bronchus. He did not improve, however, and death finally ensued due to general debility and exhaustion.

CASE III.—Mrs. A. C., sixty years of age, sick three years. She complained chiefly of attacks of shortness of breath, cyanosis, and wheezing which were likely to occur at any time during the day or

night. These attacks might recur once or many times during the day. The patient was made worse by mental anxiety and worry and acute infections of the upper respiratory tract, and she was worse in the winter, though attacks occurred in the summer also. She demonstrated no allergy. X ray of the chest revealed some old healed foci in both upper lobes. X ray of the head showed that the frontal and sphenoidal sinuses were absent. The antra were small and partly cloudy. Nasal examination revealed a bilateral chronic ethmoiditis and polypi. *Streptococcus hemolyticus* and *Staphylococcus aureus* were isolated from the sputum. Thirteen doses of a vaccine of these were given.

On December 21, 1920, bronchoscopy showed the mucous membrane of the left bronchus pinkish white and stippled with small red areas. Mucus was exuding from its lumen which was contracted and it was impossible to pass the tube except for about half the distance. The right bronchus was normal. The mucous membrane of the left bronchus was treated with ten per cent. solution of silver nitrate and five c. c. of orthoform and tannic acid mixture were deposited in its lumen. After this the patient remained free from symptoms for a little over six weeks, when, after a great deal of worry incident to business and the contracting of a severe cold in the head, her asthmatic attacks returned slightly and gradually increased in severity until on March 3, 1921, she was bronchoscoped during an attack. The left bronchus was found to be entirely occluded and its mucous membrane intensely red and swollen. After using one in one thousand adrenalin solution freely on the mucous membrane of the left bronchus, it was completely opened and the attack of asthma stopped. The mucous membrane was swabbed with a ten per cent. solution of silver nitrate and five c. c. of the orthoform and tannic acid mixture deposited in the left bronchus.

During all this time the patient was receiving vaccine every four or five days, when about March 20, 1921, an abscess of the left arm developed. This proved to be an infection from the vaccine, which had evidently not been sufficiently sterilized, as the same organisms were found in the abscess which were incorporated in the vaccine. The patient was very sick and was constantly having attacks of asthma, which ceased after the abscess was opened, except for an occasional attack. She has been very comfortable up to the present writing.

CASE IV.—Mr. J. P., fifty-two years of age, ill six years. He complained of obstructed breathing, attacks of coughing, dyspnea, and expectoration, which were worse in the winter. He had a deviated septum. Radiograph of the chest revealed a moderate infiltration and retraction in both apices (old healed lesions); aorta moderately atheromatous; paranasal sinuses and head normal. He was slightly allergic to stock *Streptococcus nonhemolyticus* protein. A specimen of sputum was not procurable. Cultures from the nose revealed nonhemolytic streptococcus and *Staphylococcus albus*. The patient was found to be slightly sensitive to autogenous suspensions of *Staphylococcus albus* but not to be *Streptococcus nonhemolyticus*. Fourteen doses of a vaccine of these were given.

Bronchoscopy revealed occasional red areas in the trachea; the left bronchus constricted in its lower portion; the mucous membrane of the right bronchus thickened and roughened, with areas of scar formation. The mucous membrane of both bronchi could not be shrunken entirely by adrenalin. Treatment consisted of ten per cent. silver nitrate solution applied to the inflamed areas and about five c. c. of orthoform and tannic acid mixture deposited at the bottom of each main bronchus. The patient was much improved but not cured.

CASE V.—Mr. M. L., twenty-nine years of age, sick six years. He complained chiefly of cough, expectoration, and heaviness in the chest, and felt worse in the winter time. He had enlarged middle turbinates and mucus dripping from the nasopharynx. An examination of the sputum revealed the presence of *Staphylococcus aureus* and the pneumococcus. He was very sensitive to autogenous suspensions of the pneumococcus.
